Sawyer, Fred A. (J'37) (BHS), Grinnell Co., Inc., 260 W. Exchange St.; *for mail*, 244 Irving Ave., Providence, R.I.
Sawyer, Gordon T. (J'41) (CEF), Student Engr., Engrg. Dept., Chrysler Corp., 12800 Oakland Ave.; *for mail*, 165 Colorado Ave., Highland Park, Mich

Sawyer, H. T. (J'40) (HLS), Mech. Engr., Bailey Meter Co., 1050 Ivanhoe Rd., Cleveland, Ohio; *for mail,* 2430—42nd Ave. N., Seattle, Wash.
Sawyer, J. G. (J'41) (AHK), Engr., Curtiss-Wright Aircraft Corp., Robertson; *for mail,* 5363-B Gladstone Pl., Normandy, St. Louis Co., Mo.
Sawyer, R. Tom ('30; '35), Sales Engr., Diesel Loco., Am. Loco. Co., 30 Church St., New York, N.Y.
Sawyer, Willits H. ('28) (CRS), Exec. Cons. Engr., 30 Broad St., New York, N.Y.
Saxby, Lewis E. ('17; '21) (CE), Administrative, Electrol, Inc., 934 Main Ave., Clifton; *for mail,* 563 Park St., Upper Montclair, N.J.
Sayer, John (J'40) (CLT), Student Engr., E. I. du Pont de Nemours & Co.; *for mail,* 219 Rayon Dr., Old Hickory, Tenn.
Sayers, Wm. W. ('01; '06) (D), Ch. Engr., Link-Belt Co., 307 N. Michigan Ave., Chicago, Ill.
Sayles, Bertram J. (A'31) (CJP), Pres., Gen. Mgr., Calorizing Co., Hill & Pitt Sts., Wilkinsburg, Pa.
Saylor, David C. ('32) (FKS), Asst. Prof. Mech. Engrg., Carnegie Inst. of Tech., Pittsburgh, Pa.
Sayre, Mortimer F. ('22) (BES), Prof. Applied Mech., Union College, Schenectady, N.Y.
Sayre, Richard L. ('26; '38) (CDJ), Ch. Engr., Heekin Can Co., 435 New St., Cincinnati, Ohio.
Scaife, J. Verner, Jr. ('40), Scaife Co., Oakmont; *for mail,* Woodland Rd., Pittsburgh, Pa.
Scanland, Boyd (J'39), Engr., Charge Design, Hutchinson Fdy. & Steel Co., D & Washington Sts.; *for mail,* 1403 N. Main St., Hutchinson, Kan.
Scanlon, Harry Charles (J'36), 70 Prospect Park, S.W., Brooklyn, N.Y.
Scavullo, Joseph J. (J'41) (BCH), Instr., Economics Dept., Stevens Inst. of Tech.; *for mail,* 532 Hudson St., Hoboken, N.J.
Schaaf, Geo. C. (J'36), Layout Man, Draftsman, Columbia Steel Rule Die Corp., 270 Lafayette St., New York; *residence,* 66-51 Freshpond Rd., Ridgewood, Brooklyn, N.Y.
Schaal, Norbert J. ('25; '35) (KLW), Box 465, Route 9, Seattle, Wash.
Schabtach, Carl (J'36) (BJS), Design Engrg., Steam Turbine Dept., Gen. Elec. Co., 1 River Rd.; *for mail,* 1918 Mayfair Rd., Schenectady, N.Y.
Schaefer, C. T. ('19; '30), Tech. Editor, *Automobile Digest,* 22 E. 12th St., Cincinnati, Ohio; *for mail,* 5722 Neosho St., St. Louis, Mo.
Schaefer, Conrad B. (J'27) (CDS), Dist. Auditor, Austin Co., 19 Rector St., New York, N.Y.
Schaefer, Earl (J'41) (BCM), Mech. Engr., Elgin Natl. Watch Co.; *for mail,* 376 E. Chicago St., Elgin, Ill.
Schaefer, F. LeRoy ('33) (CLS), Supt., Serv. Dept., E. I. du Pont de Nemours & Co., P.O. Box 1537; *for mail,* Oakwood Rd., R.F.D. 2, Charleston, W.Va.
Schaefer, Fred'k R. ('11; '25) (CDJ), Gen. Mgr., Niles Steel Products Div., Republic Steel Corp., Niles, Ohio.
Schaeffer, Emile J. (J'38) (ABC), 4608 Walther Ave., Baltimore, Md.
Schaeffer, Philip A. (J'37) (BCM), Designer, Tire-Making Mchy., B. F. Goodrich Co., Oaks; *for mail,* 3200 St. Vincent St., Philadelphia, Pa.
Schaeuble, Clifford H. (J'31) (FLS), Ch. Engr., Andrew Jergens Co., 2535 Spring Grove Ave.; *for mail,* 1610 W. Belmar Pl., Cincinnati, Ohio.
Schafer, Sidney P. ('24; '25; '35) (AJM), East. Sales Mgr., Racine Tool & Mch. Co., Racine, Wis.; *for mail,* 40 Jones St., Jersey City, N.J.
Schafer, Theodore W. D. (J'41) (CLT), Asst. to Yarn Supt., Atlantic Mills Div., A. D. Juilliard & Co., Inc., 120 Manton Ave., *Providence; for mail,* 92 Ferncrest Ave., Cranston, R.I.
Schafer, Vernon E., Jr. (J'40) (BEK), Test Engr., Diesel Eng. Div., Gen. Motors Corp., 13400 W. Outer Dr.; *for mail,* 13570 Kentucky Ave., Detroit, Mich.
Schaff, Frederic A. ('15; '26), Pres., Superheater Co., 60 E. 42nd St., New York, N.Y.
Schaffer, Bernard (J'33) (AJM), Project Engr., Am. Airlines Inc., LaGuardia Field; *for mail,* 1091 Longfellow Ave., New York, N.Y.
Schaffert, G. A. (J'40), Plant Engr., Stonecutter Mills Co., Spindale, N.C.
Schaffner, John W. ('31) (BDJ), 121 Home Ave., Oak Park, Ill.
Schaidt, Leander, Jr. (J'40) (ACE), Draftsman, Glenn L. Martin Co., Baltimore; *for mail,* 806 D Wilson Point Rd., Middle River, Md.
Schainker, Arnold (J'35) (EFP), Sales Engr., Shell Oil Co., Inc,. Shell Bldg., St. Louis; *for mail,* 7044 Tulane St., University City, Mo.
Schalla, Clarence (J'41), 3280 W. 43rd St., Cleveland, Ohio.
Schaller, Alwin ('11; '21), Gen. Mgr., McEwen Bros., Wellsville, N.Y.
Schapiro, Sylvan B. (J'26) (CKP), Asst. Gen. Plant Supt., Pan Am. Refining Corp., P.O. Box 401, Texas City, Tex.
Scharnagel, Herman J. ('19), 235 W. 22nd St., New York, N.Y.
Scharnberg, Lester N. (J'22) (CHP), Asst. Steam Engr., Gulf Oil Corp., Rm. 401, Gulf Bldg., Pittsburgh, Pa.
Scharpenberg, Charles C. ('17; '35) (EHP), 2300—18th St., Bakersfield, Calif.
Schaub, H. W. (J'40) (CHM), Engr., Worthington-Gamon Meter Co., 296 South St., Newark, N.J.
Schauer, George Alan (J'41), Exper. Tester, Diesel Engs., Fairbanks, Morse & Co., Beloit, Wis.; *for mail,* 704 Chicago St., Belvidere, Ill.
Schaum, Otto W. ('94) (CMW), Chmn., Fletcher Works, Inc., Glenwood Ave. & 2nd St., Philadelphia, Pa.
Schear, Abraham (J'39) (BCD), Specification Writer, Philadelphia Navy Yard, Bldg. No. 12; *for mail,* 3037 N. Broad St., Philadelphia, Pa.
Schechter, John P. (J'35) (CDS), Mech. Engr., Austin Co., 429 Curtis Bldg.; *for mail,* 1812 Burns Ave., Detroit, Mich.
Scheckenbach, John A. V. ('17; '21) (CJR), V.P., Charge Prod., Am. Car & Fdy. Co., 30 Church St.; *for mail,* 501 W. 113th St., New York, N.Y.
Scheel, H. V. R. ('09; '13) (CT), Propr., H.V.R. Scheel Co., 630—5th Ave., New York, N.Y.
Schefe, F. K. ('41), Plant Ch. Engr., Sheet & Tin Div., Carnegie-Ill. Steel Corp.; *for mail,* 437 Cleveland St., Gary, Ind.
Scheibe, Elias W. (J'40) (EKS), Engrg. Draftsman, Babcock & Wilcox Co., Sterling Ave.; *for mail,* 505 Wooster Rd. W., Barberton, Ohio.
Scheibel, Albert H. ('19; '35) (FKS), Stone & Webster Engrg. Corp., 49 Federal St., Boston, Mass.
Scheidemantle, Herbert S. (J'39) (FJS), Mech. Engr., Erie Forge & Steel Co.; *for mail,* 1036 W. 10th St., Erie, Pa.
Scheidt, Harry J. (J'36) (ERS), Serv. Engr., No. Equip. Co., 1945 Grove Dr.; *for mail,* 3427 Argyle Ave., Erie, Pa.
Schein, Herbert (J'40), 106-12—107th Ave., Ozone Park, L.I., N.Y.
Schell, Albert E. ('22; '35) (CDM), Engr., Mech. Design Div., Stromberg-Carlson Tel. Mfg. Co., 100 Carlson Rd.; *for mail,* 129 Stone Rd., Rochester, N.Y.
Schell, Erwin H. ('13; '21; '35) (CDM), Prof., Charge Dept. of Business & Engrg. Admin., Mass. Inst. of Tech., Cambridge, Mass.
Schell, Frederic B., Jr. ('21; '28; '35), Comptrollers Dept., Charge Costs, Firestone Tire & Rubber Co.; *for mail,* Avalon Apts., 214 N. Portage Path, Akron, Ohio.
Schell, H. B. ('41), 216 Park Pl., Brooklyn, N.Y.
Scheller, Oscar A. (J'39), 85-25—151st St., Jamaica, L.I., N.Y.
Schellhase, Frank A. (J'40) (DMS), Draftsman. Engrg. Dept., Sunbeam Elec. Mfg. Co., 225 W. Morgan Ave.; *for mail,* 1216 Edgar St., Evansville, Ind.
Schenck, Chas. ('02; '16) (BCD), Devel. Engr., Bethlehem Steel Co., 3rd & Buchanan Sts., Bethlehem, Pa.
Schenk, Einar S. (J'40), Contractors, Pier 31A, Honolulu, T.H.
Schenk, Everett M. (J'36), 37 Division Ave., Summit, N.J.
Schenk, Jan M. (J'37) (BES), Engr., De Laval Steam Turbine Co., 853 Nottingham Rd.; *for mail,* 554 Parkway Ave., Trenton, N.J.
Scher, Geo. ('25), Pres., Gen. Mgr., Weber & Scher Mfg. Co., Inc., 263 Sussex Ave., Newark, N.J.
Scherer, Francis R. ('23), Arch. & Deputy Supt. of Sch. Bldgs., Bd. of Education, 13 S. Fitzhugh St., Rochester, N.Y.
Scherer, Herman A. G. ('19; '22; '27) (BHJ), Ch. Engr., Ivers-Lee Co., 215 Central Ave., Newark; *for mail,* 71 Pine Grove Ave., Summit, N.J.
Scherer, Walter G. ('41) (KLM), Ch. Engr., Leader Iron Works, Inc., 2200 N. Jasper St.; *for mail,* 327 Keller Lane, Decatur, Ill.
Scheringer, Emil W. (J'38) (AE), Tester, Exper. Test Dept., Wright Aero. Corp., Paterson; *for mail,* 41 Lyle Ave., Tenafly, N.J.
Scherner, John ('17; '20) (FMS), Plant Engr., U.S. Rubber Co., Chicopee Falls; *residence,* 1007 Roosevelt Ave., Springfield, Mass.
Scheuble, P. A., Jr. (J'39) (CER), Sales Engrg. Dept., Jr. Engr., SKF Industries, Inc., Front St. & Erie Ave.; *for mail,* 5722 Greene St., Germantown, Philadelphia, Pa.
Schey, Ira M., Jr. (J'41), 104 North St., Harrison, N.Y.
Schick, D. Fred'k, Jr. ('31; '41) (FHS), Engr., Philadelphia Elec. Co., 900 Sansom St.; *for mail,* 4517 Locust St., Philadelphia, Pa.
Schick, Herman L. (J'34), Draftsman, Designing, Maint. & Equip., Consltd. Edison Co. of N.Y., Inc., 4 Irving Pl., New York; *for mail,* 234 Cornelia St., Brooklyn, N.Y.
Schickedanz, Louis H. (J'16) (CFS), Engr., U.S. Coal & Coke Co.; *for mail,* Gary, W.Va.
Schickel, Norbert H. ('40), 305 Cornell St., Ithaca, N.Y.
Schier, Oscar B., II ('32; '40) (CFS), Asst. Engr., Consltd. Edison Co. of N.Y., Inc., 4 Irving Pl., New York, N.Y.
Schieren, G. Arthur ('30), V.P., Chas. A. Schieren Co., 30 Ferry St.; *for mail,* The Stanhope, 995—5th Ave., New York, N.Y.
Schietinger, James Robert (J'41) (BFK), Devel. Engr., West. Elec. Co., Inc., 2500 Broening Highway; *for mail,* 2511 Harlem Ave., Baltimore, Md.
Schiffel, Joseph W. (J'41) (FKS), Indus. Fuel Engr., Pub. Serv. Elec. & Gas Co., 250 Main St., Orange; *for mail,* 98 Boyden Ave., Maplewood, N.J.
Schildhauer, Edw. ('11), Retired; 223 Bronwood Ave., Westwood Hills, Los Angeles, Calif.
Schiller, Wm. A. ('20; '35), 2626½ So. Catalina St., Los Angeles, Calif.
Schilling, Bernhard J. ('22; '35) (EFP), Mech. Engr., Petroleum Advisers, Inc., 60 Wall Tower Bldg., New York; *for mail,* 31-18—69th St., Jackson Heights, L.I., N.Y.
Schillinger, Christian ('22) (FKS), Pres., Coxe Stoker Engrg. Co., 1109 Markle Bank Bldg., Hazleton, Pa.
Schindler, D. Blair (J'39) (CJM), Engr. Apprentice, Pattern Shop, Mesta Mch. Co., West Homestead; *for mail,* 1510 Alton St., Pittsburgh, Pa.
Schinnerer, Roy L. (J'39) (ABP), c/o Tide Water Associated Oil Co., Box 811, Ventura, Calif.
Schipper, John F. (J'40), Carnegie-Ill. Steel Corp.; *for mail,* 137 Pennsylvania Ave., Clairton, Pa.
Schlachter, Carl H. ('06), Retired; 12 Crestmont Rd., Montclair, N.J.
Schlack, Bruno ('38), Engr., Philadelphia Elec. Co., 9th & Sansom Sts., Edison Bldg., Philadelphia; *for mail,* 1415 Robinson Ave., Manoa, Upper Darby, Pa.
Schlage, Ernest L. (J'38) (BJM), Devel. Engr., Librascope, Inc., Burbank; *for mail,* 1120 Norton Ave., Glendale, Calif.
Schlank, Elias ('36), Owner, Elec. Supvr. Co., 113 W. 42nd St., New York, N.Y.
Schlatter, Rudolf ('10) (BEJ), Ch. Mech. Engr., Busch-Sulzer Bros.-Diesel Eng. Co., 3300 S. 2nd St., St. Louis, Mo.
Schlatter, Rudolph P. (J'39) (BCE), Prod. Engr., Busch-Sulzer Bros.-Diesel Eng. Co., 2nd & Utah Sts.; *for mail,* 3955 Connecticut St., St. Louis, Mo.
Schleser, Erich (J'36) (HLP), Engr., Pan Am. Refining Corp.; *for mail,* Box 927, Texas City, Tex.
Schlesinger, Georg ('05) (BLM), Dir., Research Dept., Institution of Production Engineers; *for mail,* 145 Ashby Rd., Loughborough, Leics, England.
Schlichter, Fred'k Wm. ('37) (BCM), Pres., Ch. Engr., Works Mgr., Hamilton Tool Co., 9th & Hanover Sts.; *for mail,* 19 Washington Blvd., Hamilton, Ohio.
Schlick, Louis F. ('40), Ch. Engr., U.S. Lines, Inc., 25 Broadway, New York, N.Y.; *for mail,* 115 Morse Ave., Rutherford, N.J.
Schlieper, Jerome (J'41) (ADM), Mech. Engr., Union Iron Works, 600 E. William St.; *for mail,* 1139 W. Forest, Decatur, Ill.
Schlink, Fred'k J. ('17; '19; '24) (BFK), Tech. Dir., Consumers' Research, Inc., Washington, N.J.
Schlink, Norman H. (J'40) (MD), Waterford, Conn.
Schlitt, J. L. ('19; '41) (PSK). Air Reduction Co., 41 McGee Ave., Stamford; *for mail,* Christy Hill Rd., Darien, Conn.
Schlitzkus, Robt. F. (J'39) (EP), Draftsman, S. T. Johnson Co., 940 Arlington St.; *for mail,* 2467 E. 20th St., Oakland, Calif.
Schlobach, Geo. F. (J'35) (CJM), Tool Designer, Internatl. Business Mchs. Corp., Endicott; *for mail,* 71 Leroy St., Binghamton, N.Y.
Schlub, Carl F. (J'38) (BL), Jr. Mech. (Project) Engr., Air Corps, U.S.A., Wright Field, Dayton; *for mail,* Route 2, South Charleston, Ohio.
Schluderberg, Christian C. ('22; '35) (KLS), Mech. Engr., U.S. Indus. Chem., Inc., Curtis Bay; *for mail,* 5920 Burgess Ave., Baltimore, Md.
Schluderberg, Donald C. (J'39) (FKS), Calculator, Babcock & Wilcox Co., 19 Rector St.; *for mail,* 5 W. 63rd St., New York, N.Y.
Schmachtenberg, Everett (J'37) (CKS), Exper. Test Engr., Worthington Pump & Mchy. Corp., Worthington Ave., Harrison; *for mail,* 17 Hennessey Pl., Irvington, N.J.
Schmarje, Clarence F. (J'33) (FKS), Engr., Tests, Fuels & Steam Power, Carnegie-Ill. Steel Corp., Duquesne; *for mail,* 1217 Hamilton St., McKeesport, Pa.
Schmeisser, Ernest G. ('17), 3333 N. Charles St., Baltimore, Md.
Schmeisser, Wilbur J. (J'35), 1713 Sherman Ave., Evanston, Ill.

Schmeltzer, J. E. ('15; '24) (BKS), Asst. Dir., Tech. Div., U.S. Maritime Comm.; *for mail*, 4420 Brandywine St., N.W., Washington, D.C.
Schmelz, Willard (J'37), Inspr., Ward Leonard Elec. Co., South St., Mt. Vernon; *for mail*, 72 E. 190th St., New York, N.Y.
Schmid, Alfred W. ('30), Tool Engr., Robbins & Myers, Inc.; *for mail*, 2141 Harshman Blvd., Springfield, Ohio.
Schmid, B. J. (J'39) (BHS), Mech. Engr., Buffalo, Niagara & East. Power Corp., 300 Elec. Bldg., Buffalo; *for mail*, 77 Woodward Ave., Kenmore, N.Y.
Schmid, W. E. ('36), Cons. Engr., 54 boulevard Péreire, Paris 17, France.
Schmid, Wm. A., Jr. (J'26), Asst. to Pres., City Ice & Fuel Co., 6611 Euclid Ave., Cleveland; *for mail*, 2347 Tudor Dr., Cleveland Heights, Ohio.
Schmidlin, Bert E. (J'39) (BKS), 108 Fenner Ave., Clifton, N.J.
Schmidt, Albert G. ('21) (D), Rep., Harnischfeger Corp., 4439 Santa Fe Ave., Los Angeles, Calif.
Schmidt, Arthur A. ('14; '21) (BCM), West. Precipitation Corp., 1016 W. 9th St.; *for mail*, 2201 Hill Dr., Eagle Rock, Los Angeles, Calif.
Schmidt, Edward C. ('08) (BFR), Prof. Ry. Engrg., Emeritus, Univ. of Ill., Urbana, Ill.; *for mail*, 34 Rockview Ave., North Plainfield, N.J.
Schmidt, Elmer F. ('19; '29) (CEP), V.P., Oper. Mgr., Lone Star Gas Co., 1915 Wood St., Dallas, Tex.
Schmidt, Eugene A. (J'25), Field Engr., Pa. Power & Light Co., Cedar & Buttonwood Sts.; *for mail*, Box 171, Hazleton, Pa.
Schmidt, Fred'k J. (J'36), Piping & Mchy. Draftsman, Pa. Shipyards, Inc.; *for mail*, 685—8th St., Beaumont, Tex.
Schmidt, Fred'k W. (J'35) (ABE), Designing Engr. Wire Forming, Wyrstapes Co., 200 Hudson St., New York; *for mail*, 257 Linden St., Brooklyn, N.Y.
Schmidt, Geo. G. ('13; '16: '35) (KLS), Sr. Partner, Connolly & Schmidt, 10 W. 37th St., New York, N.Y.
Schmidt, Geo. W. ('36), Supt. of Power, Ind. & Mich. Elec. Co., Mishawaka, Ind.
Schmidt, Harold A. (J'41) (DKS), 3718 N. Richmond St., Chicago, Ill.
Schmidt, Harry ('38) (BJK), Exec. Engr., Fedders Mfg. Co., Inc., 57 Tonawanda St.; *for mail*, 277 Norwalk Ave., Buffalo, N.Y.
Schmidt, Harry P. ('30; '38) (BHK), Instr., Dept. of Physics, Sch. of Engrg., Pratt Inst., Ryerson St., Brooklyn, N.Y.; *for mail*, Box 177, Harrington Park, N.J.
Schmidt, John H. ('30; '36) (CDJ), Engr., Natl. Tube Co., Rm. 1714, Frick Bldg., Pittsburgh, Pa.
Schmidt, Joseph A. (J'40) (CL), Sales Engr., Mesta Mch. Co., West Homestead; *for mail*, 80 Lebanon Hills Dr., Mt. Lebanon, Pa.
Schmidt, Knute M. ('33; '39) (CDT), Engr., N. Am. Rayon Corp., Elizabethton, Tenn.
Schmidt, Richard B. (J'37), Cons. Engr., Zephyr Hill, Springfield, Ohio.
Schmidt, Roy H. (J'41) (HKS), Jr. Engr., Todd Calif. Shipbldg. Corp., Richmond; *for mail*, Westley, Calif.
Schmidtchen, Robert P. ('28) (HJM), Mech. Designer, Sperry Gyroscope Co., Manhattan Bridge Plaza, Brooklyn; *for mail*, 50 Sylvan Pl., Valley Stream, L.I., N.Y.
Schmitt, Bernard A. ('36), 3218 W. Polk St., Chicago, Ill.
Schmitt, George H., Jr. (J'40), Student Engr., New Orleans Pub. Serv. Inc.; *for mail*, 4939 S. Galvez St., New Orleans, La.
Schmoyer, Richard L. (J'37) (BGL), Project Engr., Armstrong Cork Co., South Braintree, Mass.; *for mail*, 228 N. West St., Allentown, Pa.
Schnacke, Richard N. (J'41), Mech. Engr., Aluminum Co. of Am.; *for mail*, 40 Bishop Ave., Massena, N.Y.
Schnaible, Albert P. (J'41) (AHM), Jr. Engr., Bendix Aviation Corp., South Bend; *for mail*, 538 Clay St., Mishawaka, Ind.
Schneider, Bernard R. ('27) (AGM), Mech. Engr., Chicago Pneumatic Co., Garfield; *for mail*, 621—6th Ave., Lyndhurst, N.J.
Schneider, Carl ('19; '25) (CDF), Cons. Engr., 609 Tchoupitoulas St.; *for mail*, 7711 Plum St., New Orleans, La.
Schneider, Carl A. ('26) (ELS), Sr. Engr., Ford, Bacon & Davis, Inc., 39 Broadway, New York, N.Y.
Schneider, Frank H. ('28; '36) (CFK), Research Devel. Engr., Florence Stove Co., 205 School St., Gardner, Mass.
Schneider, Fred B. (J'39) (BKR), Design Engr., Loco. Div., Gen. Elec. Co., E. Lake Rd., Erie; *for mail*, 3353 Woodlawn Ave., Wesleyville, Pa.
Schneider, Geo. Russell ('41), 711 N. Ash St., Little Rock, Ark.
Schneider, Theodore A. (J'41), 239 Chestnut St., Union, N.J.
Schneider, Wm. (J'41) (BJS), Design Draftsman, Gen. Div., Westinghouse Elec. & Mfg. Co., East Pittsburgh; *for mail*, 1311 Center St., Wilkinsburg, Pa.
Schneider, Wm. C. ('30; '35) (CLM), Asst. Supt., Waterbury Brass Goods Branch, Am. Brass Co., 26 Crane St.; *for mail*, 245 Country Club Rd., Waterbury, Conn.
Schneitter, Lee ('21; '25; '35) (EFS), Diesel Engr., Ebasco Services, Inc., 2 Rector St., New York, N.Y.
Schnitzer, A. J. (J'37), Designer, Field Rep., Orrok, Myers & Shoudy, Associates, 21 E. 40th St., New York; *for mail*, 8650—77th St., Woodhaven, L.I., N.Y.
Schnitzer, Sidney (J'35) (BHL), Mech. Devel. Engr., Boeing Aircraft Co.; *for mail*, 4731—34th Ave., N.E., Seattle, Wash.
Schoch, Edwin Foresman (J'41), Aviation Cadet, U.S. Naval Air Serv., Cadet Regiment, Rm. 119, Bldg. 711, Jacksonville, Fla.
Schock, Lewis L., Jr. (J'40) (BCH), Lt. (j.g.), Navy Yard, Brooklyn, N.Y.; *for mail*, 730 S. Queen St., York, Pa.
Schoen, John E. ('25; '35) (EJS), Prof. & Head, Dept. of Mech. Engrg., Marquette Univ., 1515 W. Wisconsin Ave., Milwaukee, Wis.
Schoenfeld, David M. ('26; '35) (FKS), Engr., Combustion Engrg. Co., Inc., 200 Madison Ave., New York, N.Y.
Schoenfeld, Edw., Jr. (J'36) (EMS), Mar. Surveyor, Am. Bur. of Shipping, Rm. 3017, Grant Bldg.; *for mail*, 3336 Brownsville Rd., Pittsburgh (10), Pa.
Schoenfeldt, Wm. ('22; '29; '35) (EFP), Engr., Shell Oil Co., Inc., 1066 Madison Ave., Albany; *for mail*, R.F.D. 2, Voorheesville, N.Y.
Schoening, Fred'k C. ('20; '23; '35) (BCM), Assoc. Mech. Engr., Design Sec., Bur. of Ord., Navy Dept., Navy Bldg., Washington, D.C.; *for mail*, 2015 S. Arlington Ridge Rd., Arlington, Va.
Schoenthaler, Robert (J'41) (EPS), Student Engr., Phillips Petroleum Co.; *for mail*, 416 Osage St., Bartlesville, Okla.
Schoerke, Douglas A. ('25; '36) (CLP), Ch. Engr., Daugherty Refinery, Div. of L. Sonneborn Sons, Inc.; *for mail*, P.O. Box 216, Petrolia, Pa.
Schoessow, Glen J. (J'32) (BCS), Dept. Head, Babcock & Wilcox Co.; *for mail*, 3463 New Portage Rd., Barberton, Ohio.
Schofield, W. Richison ('27; '32) (BLM), Dir., of Engrg., Leeds & Northrup Co., 4901 Stenton Ave., Philadelphia, Pa.
Schoij, Edgar (J'39), 2836 W. 67th St., Chicago, Ill.
Scholes, Daniel R. ('18), V.P., Aermotor Co., 2500 Roosevelt Rd., Chicago, Ill.
Scholz, Herbert H. (J'39) (BLM), Mech. Engr., Kimberly-Clark Corp.; *for mail*, 244—4th St., Neenah, Wis.
Schomburg, Louis (J'40) (ACD), 5242 Berteau Ave., Chicago, Ill.
Schonitzer, Rudolph I. ('29) (BCJ), Gen. Mgr., Reid Products Div., Stand. Products Co., 1071 Power Ave., Cleveland, Ohio.
Schooley, Harry Eugene (J'40) (JLM), Tool Engr., A. C. Spark Plug Div., Gen. Motors Corp., Dort Highway, Flint; *for mail*, 13310 Orr's Point Rd., Fenton, Mich.
Schooley, Otis L. ('30; '35), Inspr., Engr., Mutual Boiler Ins. Co. of Boston, Mass.; *for mail*, 3560 Royal Ave., Berkeley, Royal Oak, Mich.
Schorling, Henry F. ('20; '26) (KPS), Rating Div., Alco Products Div., Am. Loco. Co., 30 Church St., New York, N.Y.
Schrader, Carl (J'40) (EHK), Jr. Engr., Navy Dept., Constitution Ave.; *for mail*, 6107—14th St., N.W., Washington, D.C.
Schrader, Herman J. ('39) (BJR), Research Assoc. Prof. of Applied Mechanics, Univ. of Ill., 101 Transportation Bldg., Urbana, Ill.
Schrader, Thos. O., Jr. ('36) (FKS), Dist. Sales Agt., Erie City Iron Works, 716 Investment Bldg., Pittsburgh, Pa.
Schrader, William Christian (J'41) (BCL), Jr. Procurement Engr., Remington Arms Co.; *for mail*, 2230 North Ave., Bridgeport, Conn.
Schranz, Chas. A. ('18), Mgr., Mchy. Dept., R. D. Wood Co., 400 Chestnut St., Philadelphia, Pa.
Schranz, Fred'k G. ('16), Sales Mgr., Baldwin-Southwark Corp.; *for mail*, 6416 Overbrook Ave., Philadelphia, Pa.
Schreck, H. ('14), Asst. Ch. Engr., Charge Design, Fairbanks, Morse & Co.; *for mail*, 1208 Chapin St., Beloit, Wis.
Schreckenberger, Edw. (J'36), 4916—4th Ave., Brooklyn, N.Y.

Skaredoff, Nikolai N. (J'39), Apt. 2, 815 W. 181st St., New York, N.Y.

Skene, E. Matthew (J'41) (BM), Jr. Engr., Gen. Research, Sperry Gyroscope Co., Inc., Garden City, L.I.; *for mail,* 18 Webb Ave., Hempstead, L.I., N.Y.

Skidmore, Benj., Jr. ('24) (CHM), Pres., Gen. Mgr., Skidmore Corp., Box 309, St. Joseph, Mich.

Skilton, Harry Ingersoll ('25) (JMS), Tejadillo 7, Havana, Cuba.

Skinner, Allan D. ('13), Pres., Skinner Eng. Co., 335 W. 12th St., Erie, Pa.

Skinner, Halcyon N. ('13; '26) (FST), Plant Engr., Alex. Smith & Sons Carpet Co., Saw Mill River Rd., Yonkers, N.Y.

Skinner, Jas. C. (J'33) (ACM), 1st Lt., Air Corps, U.S.A., Dir. Mch. Shop Div., Air Corps Tech. School, Chanute Field, Rantoul, Ill.

Skinner, Jas. D. ('15) (BHS), Pres., Fuller & Co., Inc., 177 State St., Bridgeport, Conn.

Skinner, Oramel H. ('18) Treas., Thomas & Skinner Steel Products Co., 1120 E. 23rd St., Indianapolis, Ind.

Skinner, Sherrod E. ('21; '31), Olds Motor Works Div., Gen. Motors Corp., Lansing, Mich.

Sklovsky, Max ('22) (BEM), Ch. Engr., Deere & Co., Moline, Ill.

Skog, Ludwig ('35) (FKS), Partner, Sargent & Lundy, 140 S. Dearborn St., Chicago, Ill.

Skog, Ludwig, Jr. (J'39), 813 Seward St., Evanston, Ill.

Skoglund, Victor J. (J'36) (AEK), Project Engr., Pratt & Whitney Aircraft, East Hartford, Conn.

Skoog, R. W. (J'37), Engr., United Carbon Co., Inc.; *for mail,* Box 948, Borger, Tex.

Skortz, A. C. (J'34) (BCH), Ch. Inspr., J. P. Devine Mfg. Co., Mt. Vernon; *for mail,* Scheller, Ill.

Slade, Frank L. ('23; '24; '35) (CJM), Mgr., Spec. Apparatus Div., Century Elec. Co., 1806 Pine St., St. Louis; *for mail,* 532 Cornelia Ave., Webster Groves, Mo.

Slater, Charles A., Jr. (J'41) Tool Designer, Glenn L. Martin Co.; *for mail,* 900-B Wilson Point Rd., Stansbury Manor, Middle River, Md.

Slauson, Harold W. ('08; '23), 93 Walworth Ave., Scarsdale, N.Y.

Slavenak, A. J., Jr. (J'41) (EHS), Supvr. Drafting Rm. Annex, De Laval Steam Turbine Co., Nottingham Way; *for mail,* 21 Samdin Blvd., Trenton, N.J.

Slaymaker, Philip K. ('28) (BMR), Prof. Mch. Design, Univ. of Neb.; *for mail,* 425 S. 26th St., Lincoln, Neb.

Slaymaker, Robt. R. ('26; '33; '35) (BMR), Assoc. Prof. Mch. Design, Case Sch. of Applied Sci., 10900 Euclid Ave., Cleveland, Ohio.

Sledge, William Lee (J'40), Freeport Sulphur Co.; *for mail,* Box 823, Freeport, Tex.

Slee, Norman S. ('09; '13) (FKS), N.Y. Sales Mgr., Babcock & Wilcox Co., 85 Liberty St., New York, N.Y.; *for mail,* 81 Hillside Rd., Elizabeth, N.J.

Sleeman, Earl C. ('18; '30) (BJM), Ch. Engr., Detroit Seamless Steel Tubes Co., Wyoming St.; *for mail,* 7232 Kingsley St., Dearborn, Mich.

Slichter, Walter I. ('02; '12; F'41) (CHS), Prof. Emeritus Elec. Engrg., Columbia Univ., New York; *for mail,* R.F.D. 1, Schenectady, N.Y.

Slingman, Theo. D., Jr. ('28; '35) (LMT), Mgr., Dayton Rubber Mfg., Rm. 200, 11 Park Pl., New York, N.Y.

Sloan, Robert Allan (J'41), 7204 Spruce St., Upper Darby, Pa.

Sloan, Walker M. (J'37) (BCM), Gen. Foreman, Remington Arms Co., Inc., Ilion; *for mail,* 606 W. German St., Herkimer, N.Y.

Sloan, Wm. Allan ('21; '30) (EFS), Prof. Mech. Engrg., Univ. of Pa., Philadelphia, Pa.

Sloane, Alvin ('37) (BCM), Asst. Prof. Mech. Engrg., Mass. Inst. of Tech., Cambridge, Mass.

Sloane, Reginald G. ('30; '35) (EFP), Chem. Engr., Stand. Oil Devel. Co., Elizabeth, N.J.

Sloat, Benj. C. ('18; '23) (CMS), Asst. Engr., Consltd. Edison Co. of N.Y., Inc., 4 Irving Pl., *for mail,* 107 E. 48th St., New York, N.Y.

Slocomb, Charles A. (J'40), Rep. & Plumbers Asst., South Oak Plumbing Co., 6207 Oak; *for mail,* 5935 Brooklyn Ave., Kansas City, Mo.

Sluss, Alfred H. ('13), Prof. Mech. Engrg., Univ. of Kan.; *for mail,* 827 Mississippi Ave., Lawrence, Kan.

Smack, John C. ('30; '35) (BCM), Asst. Sales Mgr., Indus. Div., S.S. White Dental Mfg. Co., 10 E. 40th St., New York, N.Y.

Small, Ramond E. (J'40) (ACK), Application Engr., Turbosuperchargers, Gen. Elec. Co., 920 Western Ave.; *for mail,* 24 Baker St., Lynn, Mass.

Small, Sam (J'41) (ELP), Mech. Engr., De Laval Separator Co.; *for mail,* 28 Montgomery St., Poughkeepsie, N.Y.

Smallwood, Julian C. ('13), Assoc. Prof. Mech. Engrg. & Cons. Engrg., Johns Hopkins Univ., Homewood, Baltimore, Md.

Smart, D. L. ('37) (BCS), Charge Serv. Div., Research Dept., Detroit Edison Co., 2000—2nd Ave., Detroit, Mich.

Smart, John E. (J'39), Layout Man, Electro-Motive Corp.; *for mail,* 206 N. Waiola, La Grange, Ill.

Smart, Richard A. ('94; '00; '06) (EJK), Dist. Mgr., N. Am. Mfg. Co., 2910 E. 75th St., Cleveland, Ohio; *for mail,* 6 Bowdoin St., Worcester, Mass.

Smeal, M. W. (J'41), 858 Orlando Ave., Akron, Ohio.

Smellie, Donald G. ('28) (ACM), Ch. Engr., Hoover Co., North Canton; *for mail,* 357—23rd St., N.W., Canton, Ohio.

Smend, Wm. C. ('21), Draftsman, Stand. Brands, Inc., 595 Madison Ave., New York, N.Y.; *for mail,* 45 Cypress St., Westwood, N.J.

Smethurst, Jarvis R. ('19; '35) (FST), Plant Engr., Atlantic Rayon Corp., Lowell; *for mail,* P.O. Box 311, South Barre, Mass.

Smiley, Chas. B. (J'26) (FHJ), Gen. Foreman, Maint. Dept., Irvin Works, Carnegie-Ill. Steel Corp.; *for mail,* 1822 Warriors Rd., Pittsburgh, Pa.

Smith, Abraham E. ('16), V.P., Union Tank Car Co., 228 N. LaSalle St., Chicago, Ill.

Smith, Addison T. (J'37) (BHM), Partner (Sales Engr.), Compressed Air Products, 1060 Broad St., Newark; *for mail,* 24 Fernwood Rd., Maplewood, N.J.

Smith, Albert K. ('17; '23; '27), Design Engr., Bell Tel. Labs., 463 West St., New York, N.Y.; *for mail,* 3 Oxford Terrace, West Orange, N.J.

Smith, Albert W. ('80; '92), Dean Emeritus, Sibley College, Cornell Univ.; *for mail,* 13 East Ave., Ithaca, N.Y.

Smith, Allen C. ('02), 78 Thompson St., Ft. Trumbull Beach, Milford, Conn.

Smith, Alton Lincoln ('04), Retired; Prof. Emeritus, Worcester Poly. Inst.; *for mail,* 67 Barnard Rd., Worcester, Mass.

Smith, Arthur D. (J'39) (FKS), Engrg. Dept., Foster Wheeler Ltd.; *for mail,* 5 Kernahan Ave., St. Catharines, Ont., Can.

Smith, Arthur D., Jr. ('29; '35) (DLS), Plant Engr., RCA Mfg. Co., Camden, N.J.

Smith, Arthur R. ('22), Engr., Constr. Engrg. Dept., Managing Engr., Turbine Dept., Gen. Elec. Co.; *for mail,* 832 Union St., Schenectady, N.Y.

Smith, Beauchamp E. (J'24) (CHM), V.P., Gen. Mgr., S. Morgan Smith Co., York, Pa.

Smith, Bernard (J'38) (BCL), Asst. Ord. Engr., U.S. Navy Yard, Bldg. 47-A, Mare Island; *for mail,* 629 Euclid Ave., Berkeley, Calif.

Smith, Briton O. ('24) (BFS), Asst. Engr., Scien. Div., Gibbs & Cox, Inc., 21 West St., New York, N.Y.; *for mail,* 820—3rd Pl., Plainfield, N.J.

Smith, Bruce M. (J'37) (CJM), Devel. Engr., West. Elec. Co., Inc., 100 Central Ave., Kearny, N.J.

Smith, Carl D. ('09; '21), Engr., Charge Furnace Design & Constr., Hocking Glass Co., Lancaster; *for mail,* R.D. 1, Groveport, Ohio.

Smith, Chas. A. ('26; '30; '35) (BCF), Ch. Engr., Dir. of Research, Mex. Refractories Co., P.O. Box 271, Mexico, Mo.

Smith, Chas. E. ('21; '35), Draftsman, Consltd. Edison Co. of N.Y., Inc., 4 Irving Pl., New York; *for mail,* 48 Cumberland St., Rockville Centre, L.I., N.Y.

Smith, Chas. Herbert ('24; '28; '35) (CKP), *Student Award,* '24; Dist. Engr., C. F. Braun & Co., Alhambra; *for mail,* 29 Hacienda Dr., Arcadia, Calif.

Smith, Chas. O. (J'38) (CLS), Engr., Connected with Supt. Office, Hiram Walker & Sons, Inc., Foot of Edmund St.; *for mail,* 1424 Peoria Ave., Peoria, Ill.

Smith, Chas. Richard (A'18), Supt., Mech. Div., Am. Appraisal Co., 525 E. Michigan St.; *for mail,* 2147 N. 52nd St., Milwaukee, Wis.

Smith, Chas. S. (J'38), Mar. Surveyor, Am. Bur. of Shipping, 327 S. LaSalle St., Chicago, Ill.; *for mail,* 1226 W. Wisconsin Ave., Milwaukee, Wis.

Smith, Chetwood ('21) (FKS), Mem. of Firm, Smith & Dale, 457 Stuart St., Boston, Mass.

Smith, Clyde (J'39) (FMS), Boiler Maint. Supvr., Municipal Power Plant, City of Austin; *for mail,* 2109 La Casa Dr., Austin, Tex.

Smith, Donald A. (J'33) (CGL), Factory Mgr., F. H. Levey Co., 222 -44th St., Brooklyn, N.Y.

Smith, Donald E. (J'39) (FHS), Cadet Engr., Bailey Meter Co., 1050 Ivanhoe Rd., Cleveland; *for mail,* 2104 Alton Rd., East Cleveland, Ohio.

Smith, E. Lovell ('28) (BCM), Ch. Engr., Package Mchy. Co., Birnie Ave., Springfield; *for mail,* 148 Colony Rd., Longmeadow, Mass.

Smith, Earl B. ('32) (BCK), Prof. Mech. Engrg., College of the City of N.Y., 140th St. & Amsterdam Ave., New York, N.Y.

Smith, Earle E. ('24; '30; '35) (BJP), Dir. of Serv., Natl. Tube Co., Magnolia Bldg., Dallas, Tex.

Smith, Eastman ('22; '27; '35) (BCM), Instrument Engr., Pioneer Div., Bendix Aviation Corp., Bendix; *for mail,* 37 Courier Pl., Rutherford, N.J.

Smith, Edric Brooks ('13; '35), Business Mgr., Rockefeller Inst. of Medical Research, 66th St. & York Ave., New York, N.Y.

Smith, Ed Sinclair ('23; '31) (BHL), *Junior Award,* '30; Pat. Agt., C. J. Tagliabue Mfg. Co., 550 Park Ave., Brooklyn; *for mail* 114-57—176th St., St. Albans, L.I., N.Y.

Smith, Edw. W. P. ('39) (BJM), Cons. Engr., Lincoln Elec. Co., 12818 Coit Rd., Cleveland; *for mail,* 3580 Blanche Rd., Cleveland Heights, Ohio.

Smith, Edwin D. ('14) (CDS), Plant Engr., Natl. Cash Register Co., Main & K Sts., Dayton, Ohio.

Smith, Edwin R. ('21; '35) (BCM), V.P., Gen. Mgr., Seneca Falls Mch. Co., 314-40 Fall St., Seneca Falls, N.Y.

Smith, Elliott Dunlap ('40) (CLM), Master of Saybrook College, Prof. of Economics, Yale Univ., New Haven, Conn.

Smith, Elliott E. ('25) (FKS), Ch. Oper. Engr., Suburban Plant, Scranton Elec. Co.; *for mail,* 1516 N. Webster Ave., Scranton, Pa.

Smith, Elmer ('13) (CES), Steam Turbine Specialist, Gen. Elec. Co., 140 Federal St.; *for mail,* 70 Pinckney St., Boston, Mass.

Smith, Elwyn L. ('19; '25; '34), Mem. of Firm, L. C. Smith & Corona Typewriters, Inc., 701 E. Washington St., Syracuse, N.Y.

Smith, Eric Hooper ('32; '38) (FJS), Head, Research & Devel. Div., Riley Stoker Corp., 9 Neponsey St., Worcester; *for mail,* 25 St. James Rd., Shrewsbury, Mass.

Smith, Eugene W. (J'41) (BHP), Engr., Republic Natural Gas Co., 1505 Federal St.; *for mail,* 4319 Lafayette St., Dallas, Tex.

Smith, Francis C. ('37; '41) (ELS), Editor, *Southern Power and Industry,* W.R.C. Smith Publ. Co., 1020 Grant Bldg., Atlanta, Ga.

Smith, Frank E. ('31) (ADE), Ch. Engr., Mineral Separation Div., E. I. du Pont de Nemours & Co.; *for mail,* 848 College Ave., Niagara Falls, N.Y.

Smith, Fred Bradshaw (J'36) (BDM), Jr. Mech. Engr., U.S. War Dept.; *for mail,* P.O. Box 65, Watervliet, N.Y.

Smith, Geo. G. (J'38), Engr., Charge Design, Bell Tel. Labs., Inc., 463 West St., New York, N.Y.

Smith, George L. (J'31) (BEF), Diesel Eng. Designer & Calculator, Fairbanks, Morse & Co.; *for mail,* 525 Kenwood Ave., Beloit, Wis.

Smith, Geo. W. (J'38) (CDM), Indus. Engr., Westinghouse Elec. & Mfg. Co.; *for mail,* 908 W. Spring St., Lima, Ohio.

Smith, Geo. Wetherall ('29; '35), Gen. Mgr., Hagan Corp., 502 Bowman Bldg.; *for mail,* 1121 Wightman St., Pittsburgh, Pa.

Smith, Gerald E. (J'37), 52 Parkway Ave., Toronto, Ont., Can.

Smith, Gerard L. (J'36) (CJM), Indus. Engr., York Ice Mchy. Corp., Roosevelt Ave.; *for mail,* R.D. 7, York, Pa.

Smith, H. Gordon ('30) (FPS), Power & Mech. Consultant, E. I. du Pont de Nemours & Co., P.O. Box 270, Sylacauga, Ala.

Smith, H. Pearson ('35; '35) (BLS), Plant Engr., C. H. Dexter & Sons, Inc., Windsor Locks, Conn.

Smith, H. Raymond ('16), Mech. Engr., Raymond Concrete Pile Co., 140 Cedar St., New York, N.Y.

Smith, Harold A. ('32; '41) (EPS), Supt. of Utilities, Stand. Oil Co. (Ind.), Sugar Creek, Mo.

Smith, Harold L. ('29) (EFS), Mech. Engr., Buffalo, Niagara, Elec. Corp., Elec. Bldg., Buffalo; *for mail,* Freeman Rd., Orchard Park, N.Y.

Smith, Harold T. (J'41) (JKS), Jr. Mech. Engr., Consltd. Steel Corp., Maywood; *for mail,* 6128 Orchard Ave., Huntington Park, Calif.
Smith, Harry A. ('29; '35) (BCS), Pres., Engrg. Specialties Co., Inc., 39 Cortlandt St., New York, N.Y.
Smith, Harry J. ('21) (BEJ), Engr. of Constr., Gas Dept., Pac. Gas & Elec. Co., 245 Market St.; *for mail,* 201 Wawona St., San Francisco, Calif.
Smith, Hartley Le H. ('28) (BFK), Ch. Engr., Testing Bur. Williamsburg Power Plant Corp., 500 Kent Ave., Brooklyn, N.Y.
Smith, Henry R. ('30), Mar. Supt., Colonial Beacon Oil Co., Everett; *for mail,* 9 Staples St., Melrose, Mass.
Smith, Henry S. ('19) (FJP), Cons. Engr., Linde Air Products Co., 30 E. 42nd St., New York, N.Y.
Smith, Herbert J. ('13; '26), Supt., Treadwell Tool Co.; *for mail,* 675 Bernardston Rd., Greenfield, Mass.
Smith, Howard W. ('92; '18) (BJM), Box 349, Ellwood City, Pa.
Smith, Hugh T., Jr. (J'37) (MRT), Indus. Engr., Eastman Kodak Co., 1669 Lake Ave.; *for mail,* 87 Brooks Ave., Rochester, N.Y.
Smith, Miss Irma M. (J'38) (ACM), Prod. Supvr., R. G. Smith Tool & Mfg. Co., 245 South St., Newark, N.J.
Smith, Irvine W. (J'38) (BJM), Lecturer, Univ. of Toronto; *for mail,* 40 Hazelton Ave., Toronto, Ont., Can.
Smith, Ivan Lee (J'41) (FPS), Mech. Engr., Port Arthur Works, Tex. Co.; *for mail,* 3041 Procter St., Port Arthur, Tex.
Smith, J. Darrell ('30) (FRS), Mech. Engrg. Dept., Philadelphia & Reading Coal & Iron Co.; *for mail,* 317 N. 19th St., Pottsville, Pa.
Smith, J. F. Downie ('24; '33; '35) (BCK), Research Engr., Research Div., United Shoe Mchy. Corp., Balch St., Beverly, Mass.
Smith, J. Jos. (J'36), U.S.N., U.S. Naval Oper. Base, Unit X66, Platoon 131, Norfolk, Va.; *for mail,* Apt. 1P, 25-10—30th Rd., Astoria, L.I., N.Y.
Smith, Jas. U. ('28) (B), Retired; 2477 Virginia St., Berkeley, Calif.
Smith, John F. ('39) (BCM), Pat. Counsel, Compo Shoe Mchy. Corp., 150 Causeway St., Boston, Mass.
Smith, John Hays ('22) (CHS), Cons. Engr., 6521 Darlington Rd., Pittsburgh, Pa.
Smith, John P. (J'40) (BKS), Apprentice Engr., Bailey Meter Co., 1050 Ivanhoe Rd.; *for mail,* 2962 E. 79th St., Cleveland, Ohio.
Smith, John W. (J'40) (BHL), Mech. Draftsman, Giffels & Vallet, Inc., Naval Oper. Base, Naval Air Sta.; *for mail,* Apt. B-5, 3807 Granby St., Norfolk, Va.
Smith, Kenneth M. (J'39) (DKM), Design Engr., Plant Engrg. Dept., Caterpillar Tractor Co., Peoria; *for mail,* Rome, Ill.
Smith, L. Golden ('23; '27; '35) (CFS), Asst. to Gen. Supt., Consltd. Gas, Elec. Light & Power Co. of Baltimore, Lexington St.; *for mail,* 3508 Newland Rd., Baltimore, Md.
Smith, LaRue ('39) (HLS), Pres., Smith-Monroe Co., 1910-12 S. Main St., South Bend, Ind.
Smith, Lester C. ('40) (BDF), Asst. Ch. Engr., Spencer Turbine Co., Hartford, Conn.
Smith, Lester E. (J'41), Student Engr., Gen. Elec. Co., 1 River Rd.; *for mail,* 1613 Ave. A, Schenectady, N.Y.
Smith, Lewis Cheyney, Jr. (J'39) (A), Test Engr., Wright Aero. Corp.; *for mail,* 674 E. 29th St., Paterson, N.J.
Smith, Lewis F. (J'41) (ABE), Ensign, U.S.N.R., Instr., Power Plant Div., Ground Sch., Naval Air Sta., Pensacola, Fla.
Smith, Lloyd Lyman ('20), Mgr., Lloyd L. Smith Power Plant Equip., 605 Plymouth Bldg., Minneapolis, Minn.
Smith, Louis H. V. (J'40), Student Engr., Am. Mch. & Fdy. Co., 2nd Ave. & 51st St.; *for mail,* 55 Halsey St., Brooklyn, N.Y.

STUDENT MEMBERS

THE following roster of names of Student Members of The American Society of Mechanical Engineers, grouped under the Student Branches to which they belong, was the complete list on file at the Society headquarters on December 19, 1941.

University of Akron

Acker, L. W.
Beckwith, C. R.
Bishop, R. I.
Bracken, L. B.
Brown, F. R.
Burkley, J. K.
Caillet, G.
Cartwright, R.
Dudugjian, C.
Frye, E. R.
Fullmer, F. L.
Gitter, P. L.
Haren, R. J.
Harris, Z. N.
Hart, J. B.
Hartz, M. E.
Kallgren, R. M.
McCarthy, R. O.
Moats, E. R.
Parseghian, G. A.
Pope, J. T.
Sprinkle, D. L.
Stankard, J. M., Jr.
Staudt, R. C.
Stein, S.
Sutton, J. H.
Upp, R. F.
Waddell, J.
Wilt, H. E.
Woehl, F. M.
Wolf, E., Jr.

Alabama Polytechnic Institute

Allen, J. W.
Ashmore, W. H.
Bean, E. C.
Bentley, W. C., Jr.
Brakeman, R. E., Jr.
Callaway, R. C., Jr.
Chisholm, R. C.
Clements, R. L.
Cohen, B.
Daniel, W. D., Jr.
Dubberley, C. A.
Dunn, C., Jr.
Fuller, F., Jr.
Gaillard, J. F., Jr.
Gaston, J. E., Jr.
Grace, M. F.
Greeson, R. O.
Grimes, J. D.
Gwillim, R. C.
Hancock, L. H.
Jones, E. O., Jr.
Kelley, W. D.
Kelly, C. H.
Lande, I. M.
Layfield, C. B., Jr.
Main, J. F.
Manci, F. J.
Martin, T. W.
Merrill, A. E.
Morton, S. M.
Moss, F. F.
Mullin, A. D., Jr.
Nigosian, A. J.
Overbey, C. A.
Owen, W. G.
Peterson, B. G.
Reynolds, H. W.
Richter, W. C.
Riddick, W. R.
Romanos, A. R.
Sahag, L. M., Jr.
Smith, G. L.
Stan, L. E., Jr.
Suttle, J. F.
Tankersley, G. J.
Tindal, L. V.
Trammell, W. H.
Wagner, E. A.
Weintritt, P. L.
Willis, W. J.

University of Alabama

Andes, H. D.
Christiano, A.
Edwards, B. W.
Farinella, C. C.
Fish, J. T.
Fitts, F., Jr.
Forster, H. T.
Fose, R. J., Jr.
Fritzinger, W. L.
Genovese, R. E.
Hamil, J. C.
Hill, J. A.
Hoffman, R. V., Jr.
Holston, R. J.
Jordan, W. D.
Joseph, E.
Kevorkian, S.
Kiskis, J. E.
Lawrence, S. H.
Loos, A. H.
Martynowicz, C. S.
May, J. F.
Meisinger, W. O., Jr.
Michalko, P.
Miller, E. E.
Murphy, W. M.
Ollinger, H. L., Jr.
Parks, A. J.
Patterson, W. F.
Pfeifer, H. J.
Porter, C. C.
Rosenberg, J.
Salemme, V. J.
Smith, W. F.
Snow, W. A., Jr.
Sulonen, O. O.
Tartaglia, F. E.

University of Arizona

Bayless, E. F., Jr.
Bigglestone, H. C., II
Buell, D. N.
Cardon, H. P.
Currie, G. D.
Diehl, A. R.
Dunaway, R. J.
Fiedler, F. S.
High, R. G.
Kempton, M. L.
Kerr, D. M.
Kimsey, W. L.
Kinkead, J. C.
Lyons, J. O.
Mullen, R. C.
Nelms, C. E.
Stephens, R. A.
Thomas, L. G.
Weaver, R. O.

University of Arkansas

Bacher, A. H.
DeLamar, B. B.
Franklin, P. E.
Gammill, W. R.
Garner, E. R.
Gilbert, S. K.
Grant, W. H.
Hall, R. D.
Hennig, E. F.
Hutchison, E. S.
Isely, F. D.
Jacks, J. W.
Kunkel, C. E.
Nelson, R. L.
Peters, J. C.
Robinson, R. H.
Teal, A. P.
Toone, J. A., Jr.
Willms, H. C.
Zilinski, J. W.

University of British Columbia

Barton, E. S.

CONSULTING SERVICE INDEX

This section groups geographically those members engaged in independent consulting practice and is a list of those who sent in the reply card for this Index which accompanied the Membership List card sent out in September 1941.

It is confined to consultants either as individuals or connected with consulting organizations and includes Consulting Engineers, Management Consultants, Specialists, Patent Lawyers, Patent Attorneys and Patent Agents, Constructors and Contractors.

Only those rendering service independent of or uninfluenced by the manufacture or sale of a product are being listed. Any omissions as may be noted are due in most cases to failure on the part of members to furnish the information desired.

Supplementing this general Index and immediately following it, is a Classified Specialty List of a number of the consultants (indicated by an asterisk in the geographical list) advertising their specialized lines of practice.

Both this Index and the Specialty List should be helpful in the selection of consultants . . . . by location and by specialty.

Consulting Engineers
Management Consultants

CONSULTING SERVICE

Patent Attorneys
Constructors—Contractors

All of the engineers listed are strictly independent professional consultants and have no manufacturing or sales connections.

RATE From one to five listings in the Classified Specialty List, $10.00, which includes name and address in Alphabetical List. Additional listings $1.00 each.

THE feature of this section is the Classified Specialty List, which is arranged alphabetically by subject headings. The method of classification is to list by specific specialty and sub-list by function performed. The advice or services of a specialist thus can be obtained without delay or confusion.

When seeking consultants for a given specialty, for example, Steam Power Plants, look unde " POWER PLANTS, STEAM" and under this heading and its subheadings are listed those specializin- in the design, location, supervision, layout, test, etc., of such a project. Select one or more names and refer to the Alphabetical List in the center of each page for addresses.

SPECIALTY LIST

Air Conditioning Systems (Design)
Ledsham, William H.
Lindstrom, Alvin L.
Ophuls, Fred
Wyatt, DeWitt H.

Air Conditioning Systems (Operation)
Ledsham, William H.

Air Pollution
Christy, William G.

Aircraft Controls, Hydraulic (Design and Development)
Miller, Norman E.

Alkali Manufacturing Plants (Design and Operation)
Trump, Edward N.

Ammonia Manufacturing Plants (Design)
Trump, Edward N.

Anti-aircraft Artillery (Automatic Directors)
Morse, Robert V.

Appraisals
(*See also Industrial Plants, Power Plants, etc.*)
Carter, Emmett B.

An Improved Hand-Fired Furnace for High-Volatile Coals

By J. R. FELLOWS[1] and J. C. MILES,[2] URBANA, ILL.

This paper describes a furnace designed to burn high-volatile coal in two distinct phases: (1) Green coal is reduced to coke in the forward part of the furnace called a coking chamber; (2) when refiring is necessary, the resulting coke is pushed forward and down an inclined grate, where it burns as a smokeless fuel. The volatile gases from the coal pass under a baffle wall through which secondary air is admitted. Burning of the volatile gases occurs above the bed of hot coke. Air for coking the green coal and for burning the coke, as well as secondary air, is admitted through separate inlet openings. The furnace was found to produce no smoke and operated well on a variety of fuels. The temperature of the baffle wall was found to be proportional to the amount of air admitted to the coking chamber. The results indicate this method of burning bituminous coal is applicable to all types of hand-fired equipment, such as stoves, furnaces, and water heaters.

The enormous amount of bituminous coal in the United States together with its wide geographical distribution makes it the most economical fuel for a large percentage of the population. That much of this coal will continue to be burned in low-cost hand-fired equipment is evidenced by the fact that approximately 7,000,000[3] coal- and wood-burning heating stoves were sold in the United States during the period from 1925 to 1937, and over 1,400,000 during the year 1937 alone, according to the latest report of the Census of Manufacturers.

The primary objections to the use of high-volatile coal in most hand-fired equipment comes from the amount of attention required and from the quantity of smoke produced. For both of these ills the stoker provides a satisfactory solution. However, until the use of stokers is economically feasible for a larger percentage of our population, the smoke palls are apt to hang over the poorer districts of most cities in the bituminous-coal area. If hand firing of high-volatile coal is prohibited by law, those least able to pay are forced to buy a premium fuel. This is made more significant by the fact that approximately 42 per cent[4] of the 29,000,000 family units in the United States, during the year 1937, had an income of less than $1000. The need for improving hand-fired bituminous-coal stoves and furnaces, with the object of eliminating smoke, increasing efficiency, and reducing the attention required, is quite evident.

There are two possible solutions for the problem of smoking fires: (1) that of processing the fuel, and (2) that of improving the furnace or stove. Fuel-processing operations such as coking and briquetting to produce a smokeless product must of necessity add to the cost of the fuel by virtue of those operations and the added transportation and handling costs. Therefore, the more logical solution of the smoke problem for families having low incomes would seem to be the development of suitable bituminous-coal-burning equipment, rather than reduction of the fuel to a "smokeless" form.

In this connection, it is interesting to note that, in the early stages of its development, the simple kerosene lamp was similarly handicapped, in that it produced much smoke. The present kerosene lamp which we are prone to regard as a crude primitive device is the result of very elaborate and painstaking research done more than half a century ago. Those interested are referred to a book[5] by Stepanoff, for which he was awarded the Nobel prize. Attempting to improve the oil rather than the lamp in this case would doubtlessly have proved futile.

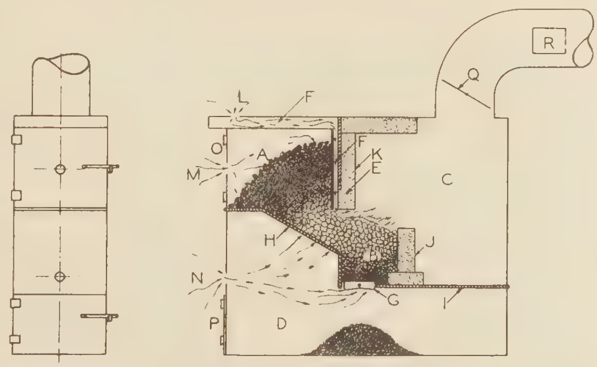

Fig. 1 Schematic Section of Test Furnace

- A Coking chamber, intermittently charged with green coal by hand firing
- B Coke-burning chamber into which coke is pushed before refilling coking chamber with green coal
- C Combustion chamber
- D Ashpit
- E Baffle wall
- F Secondary-air passage
- G Shaking grate

- I Dead plate
- J Back stop
- K Refractory block
- L Secondary-air inlet
- M Coking-air inlet
- N Undergrate-air inlet
- O Firing door
- P Ash door
- Q Cross damper
- R Check damper

The requirements for obtaining smokeless combustion of high-volatile coal have long been known, and have been briefly summarized by various authors as follows:

(*a*) Sufficient temperature for ignition.
(*b*) Sufficient air for oxidation.
(*c*) Thorough mixing of volatile gas and air.
(*d*) Sufficient time to complete oxidation.

It seems incredible that these few requirements could not be satisfied in some simple unit.

A good stove or furnace should incorporate those features essential to comfort, convenience, cleanliness, and economy. The major requirements are as follows:

---

[1] Assistant Professor of Mechanical Engineering, University of Illinois.

[2] Instructor in Mechanical Engineering, University of Illinois. Jun. A.S.M.E.

[3] "The Stove Market," editorial, *Coal Heat*, vol. 38, no. 6, December, 1940, p. 36.

[4] "Statistical Abstract of the United States—1939," U. S. Bureau of the Census, Washington, D. C., table of "Consumer Incomes," p. 313.

Contributed by the Fuels Division and presented at the Semi-Annual Meeting, Kansas City, Mo., June 16–19, 1941, of The American Society of Mechanical Engineers.

[5] "Oil Burning," by H. A. Romp, Martinus Nijhoff, The Hague, Holland, 1937; reference is made on page 87 to "Grundlagen der Lampentheorie," by Stepanoff (1894).

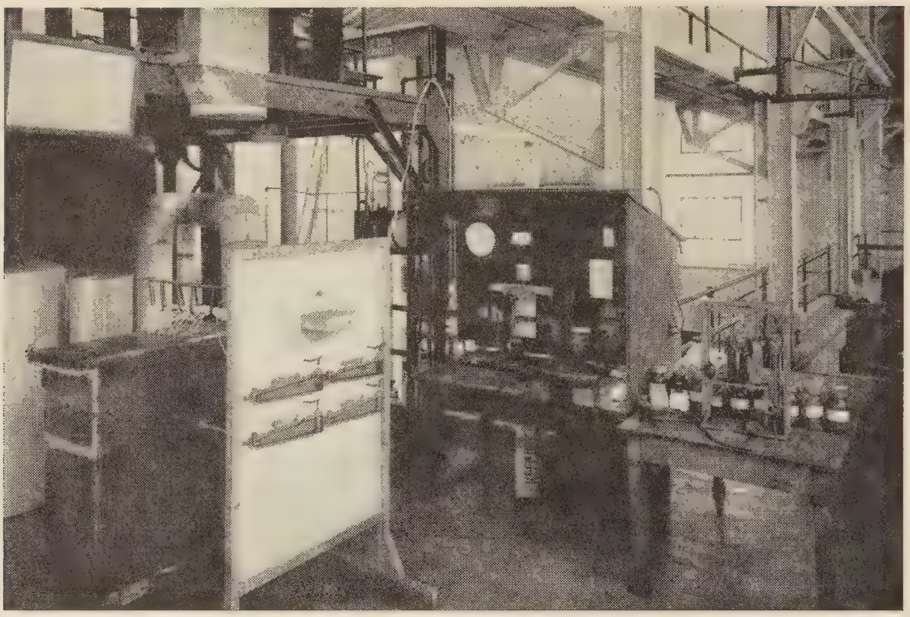

Fig. 2 Arrangement of Test Apparatus

1 A large fuel capacity to eliminate frequent firing.
2 Adaptability to simple automatic temperature control.
3 Ashpan of sufficient size so that cleaning is not too frequently required.
4 Complete combustion with a minimum of excess air.
5 Smokeless operation.
6 Ability to burn fuel of various grades and sizes.

The furnace discussed in this paper was developed as the result of an attempt to incorporate these features in a simple unit for burning high-volatile coal. The furnace was designed by the authors and was tested in the Mechanical Engineering Experiment Station of the University of Illinois.[6]

The object of the tests was to determine how many of the different types of solid domestic fuels could be burned successfully in a unit of this type.

[6] The Engineering Experiment Station is under the direction of Dean M. L. Enger. Professor A. P. Kratz is in charge of research in mechanical engineering.

Description of Furnace

The principal features of the furnace design are shown in Fig. 1. The furnace was made of 1/4-in. firebox-steel plate in the shape of a simple rectangular box and was arranged in such a way that the proportional volumes of the coking chamber and the coke-burning chamber, and the slope and position of the inclined grate could be easily changed. The furnace was made airtight by welding the plates at the edges. Over-all dimensions were width, 16 inches; height, 41 inches; and length, 48 inches.

The baffle wall consisted of five narrow channel-shaped heat-resisting castings, attached to a supporting plate of 5/8-in. firebox steel by means of single-pin brackets. The castings provided air passages for secondary air which entered through the double roof and was discharged at the bottom of the baffle wall. A refractory block was placed at the rear of the baffle wall to shield it from radiant heat from the combustion chamber.

The inclined grate was arranged to facilitate the transfer of coke from coking chamber to coke-burning chamber. This in-

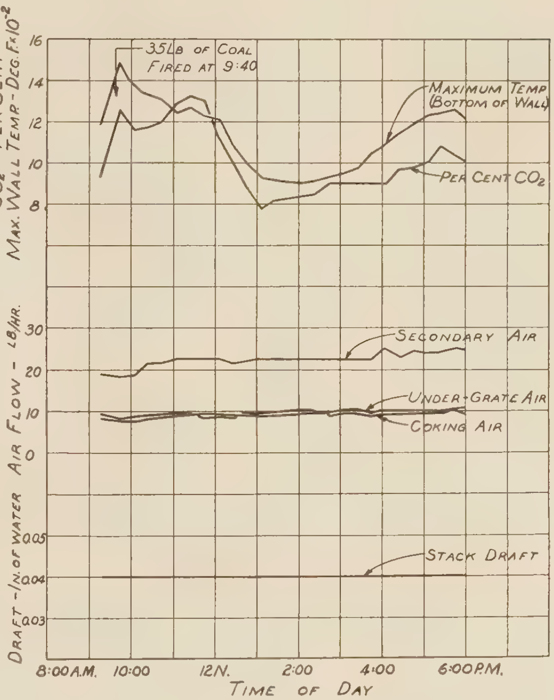

FIG. 3 GRAPHICAL LOG OF TEST NO. 10; FRANKLIN COUNTY, ILLINOIS, COAL

clined grate was provided with 1/4-in. holes on 1-in. centers for a distance of 6 in. nearest the baffle wall. The purpose of the holes was to promote sufficient combustion in the coke at this region to maintain below the baffle wall an ignition temperature high enough to assure ignition of all gases passing from the coking chamber.

Furnace Operation. The furnace was designed to burn high-volatile coal in two distinct phases and the operation is as follows: (1) A charge of green coal (about 35 lb) is converted to coke in the coking chamber; (2) when refiring is necessary, the coke is pushed down the inclined grate into the coke-burning chamber before a new charge of green coal is placed. While the green coal is being converted to coke, the volatile gases evolved pass beneath the baffle wall, where they become mixed with the secondary air entering through the baffle wall. The mixing occurs just above the bed of burning coke, in a region where the temperature is high enough to ignite the mixture.

The rate of distillation of gases from the green coal is determined by the amount of primary air entering the coking chamber. The rate at which the coke burns on the grate is determined by the amount of air admitted below the grate. Sufficient air to burn the volatile gases is admitted through the baffle wall.

By proportioning properly the three air-inlet openings, the green coal is completely coked before the coke from the previous charge is all consumed on the grate. With this cycle of operation a region of high temperature is always maintained, through which the volatile gases must pass. By supplying sufficient secondary air through the baffle wall, conditions are ideal for complete combustion of the volatile or smoke-forming content of the coal. The air flow through all three inlet openings and, consequently, the rate of combustion are controlled by use of a check or cross damper as in any conventional furnace.

Instruments and Calibration. Temperatures existing in the baffle wall were measured by means of thermocouples, made by peening the ends of No. 22 B.&S. gage Chromel and Alumel wires

into holes drilled $^1/_4$ in. apart in the alloy castings. The thermocouples were spaced at varying distances from the bottom of the baffle wall. The wires were protected by porcelain insulators and brought out the top of the furnace to a cold-junction box mounted on a panel a short distance from the furnace. Copper-wire extensions were run from the cold-junction box to a selector switch and a potentiometer. The calibrations were checked by measuring the melting points of several chemically pure metals with a thermocouple made exactly as those in the test furnace. A mercury-in-glass thermometer was used to determine the temperature at the thermocouple cold junction.

Flue-gas analyses were made with a standard Orsat apparatus, and thin-plate orifices were used to measure the flow of air through the three separate inlets.

The orifices used were made by turning smooth holes in flat 23-gage-steel plates. The pressure drop through each orifice was measured with an inclined draft gage graduated in hundredths of an inch of water. A similar gage was also used for measuring the chimney draft at the outlet from the combustion chamber. The chimney draft was regulated by means of a check-draft damper and a cross damper in the smoke pipe. The general arrangement of the equipment is shown in Fig. 2.

Test Procedure

Tests were made on eleven types of fuels, representing the general range of types common in domestic firing. A test was made on each of these at a low combustion rate, and a second test was made at a high combustion rate, except in the cases of sawdust and wood scrap which were burned at the low rate only. The combustion rate was controlled by regulating the stack draft. During the low-rate tests, the stack draft was maintained at 0.04 in. of water and a draft of 0.12 in. of water was maintained during the high-rate tests. This range of draft was chosen as representing approximately the normal range encountered in domestic practice. The fuel was not disturbed during any test.

For each fuel tested, the proper orifices were selected so that the combination would give the highest average CO_2 consistent with completely smokeless operation. With any given fuel, the low-combustion-rate test was run first, as it was found to be more difficult to obtain smokeless combustion at this rate. The orifice combination which proved satisfactory for the low rate of combustion was also used for the high rate, thus only one orifice combination was used for each fuel.

Before starting a test, the furnace was fired with the kind of fuel to be tested in order that the residual coke would be from the fuel under test. The coke was broken up with an ordinary poker and the greater part pushed down the inclined grate into the coke-burning chamber. Sufficient coke was left on the lower part of the inclined grate to prevent any of the fresh charge from passing the lower edge of the baffle wall.

Immediately after placing a charge of fuel, the stack draft was adjusted to the desired value, and the doors and all places where possible leakage might occur were sealed with furnace cement. Temperatures, draft-gage readings, flue-gas analyses, and smoke observations were made at 20-min intervals. Smoke observations were made by placing an ordinary light bulb inside the stack or by observing the top of the stack against the sky. Samples were taken and proximate analyses were made of all fuels with the exception of sawdust and wood scrap. The refuse from each fuel was analyzed for unburned carbon.

Results of Tests

General data pertaining to the fuels and conditions are given in Table 1. General results are given in Table 2. Fig. 3 shows a typical graphical log.

The primary objectives were to determine whether all major types of fuel could be burned smokelessly and to measure the furnace-baffle-wall temperatures. More extensive tests are to be made to compare the performance of different fuels under a wider range of operating conditions. Furnace efficiency as cal-

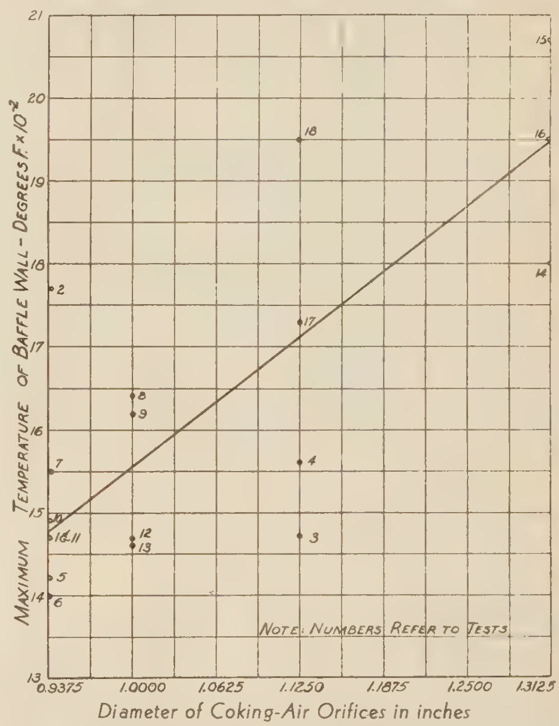

Fig. 4 Relation of Coking-Air-Orifice Size to Maximum Baffle-Wall Temperature

culated from heat losses was not determined, since the flue-gas and residue analyses give ample indication of the combustion efficiency. For the purpose of obtaining smokeless operation, there was no point in using coke or anthracite in this type of furnace. These fuels were tested, however, to see if they could be successfully burned.

Temperatures in the Baffle Wall. The temperatures existing in the baffle wall were found to be proportional to the amount of air admitted to the coking chamber. This finding is logical since combustion in the coking chamber can proceed no faster than the supply of air will permit. Fig. 4 shows the relationship between coking-air-orifice size and maximum temperature of the baffle wall. No definite curve could be drawn to represent the test points, but there is a definite tendency for the higher baffle-wall temperatures to be associated with the larger flows of air to the coking chamber. The results, shown in Fig. 4, are incidental, since no tests were run specifically to determine this relationship. The latter could be more effectively established by a series of tests involving only one fuel.

During the operating cycle, a period of high baffle-wall temperature occurred at the time the coke was being pushed down, preliminary to firing a fresh charge of green coal. While the door was open, rapid oxidation occurred at the surface of the coke bed. This initial peak in wall temperature, coincident with the time of firing, is very evident in all the graphical logs.

The temperatures measured in the lower part of the baffle wall indicate the necessity for using special heat-resisting alloys or refractories for this part of the structure. The tem-

perature gradient in the baffle wall,[7] shown in Fig. 5, indicates the necessity for using a special sectional construction to resist warping.

Smoke. Observations made at 20-min intervals showed that no smoke whatever was produced during test runs with any of the fuels used, with the exception of sawdust and wood scrap, for which very light smoke was seen on one occasion only during each of the tests of these fuels. A total of 406 observations were made during which 784 lb of fuel were burned, thus proving that high-volatile coal can be burned in this type of furnace without the formation of smoke.

For each type or kind of fuel, it was necessary to determine by experiment the best combination of orifice sizes to be used. The coking-air orifice was made sufficiently small to prevent the wall temperatures from exceeding a safe value. An undergrate orifice was then selected which would supply sufficient air below the grate to consume the greater part of the coke in the coke-burning chamber by the time the coking operation was complete. With these orifice sizes determined, a secondary-air orifice was selected such that the secondary-air supply was ample to prevent the

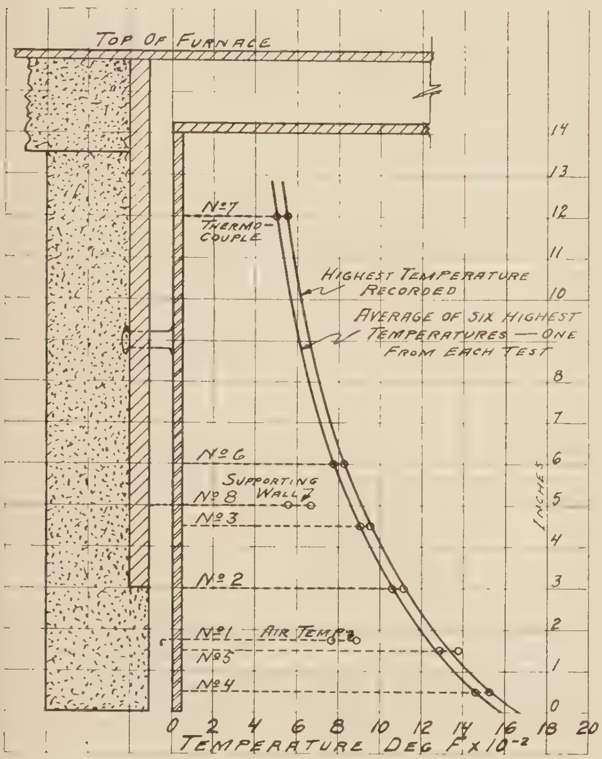

FIG. 5 TEMPERATURE GRADIENT IN BAFFLE WALL

formation of smoke throughout the operating cycle. During the preliminary work required to determine the proper orifice combination for a given fuel, smoke frequently occurred as a result of too small a secondary-air orifice.

With high-volatile coal, the peak demand for secondary air occurred approximately 1 hr after recharging the furnace. Since the rate of volatilization was highest at that time, it was generally coincident with the highest CO_2 content in the flue gas.

Fuel-Burning Rate. Using bituminous coal, the average fuel-burning rate was 7.5 lb per hr with 0.12 in. draft, and 4.2 lb per hr with 0.04 in. draft. These rates are comparable with those of updraft furnaces of similar physical dimensions. The minimum burning rate of 1.5 lb per hr was established during test No. 7 in which 18 lb of coal were sufficient to maintain slow combustion for 12 hr.

Fuel Sizes. The range in size of coal fired was not great enough to establish the effect of fuel size on furnace performance. It is significant, however, that screenings were successfully burned as well as 1 × 2-in. nut coal. During other tests 2 × 3-in. nut coal has been successfully burned. It therefore appears that

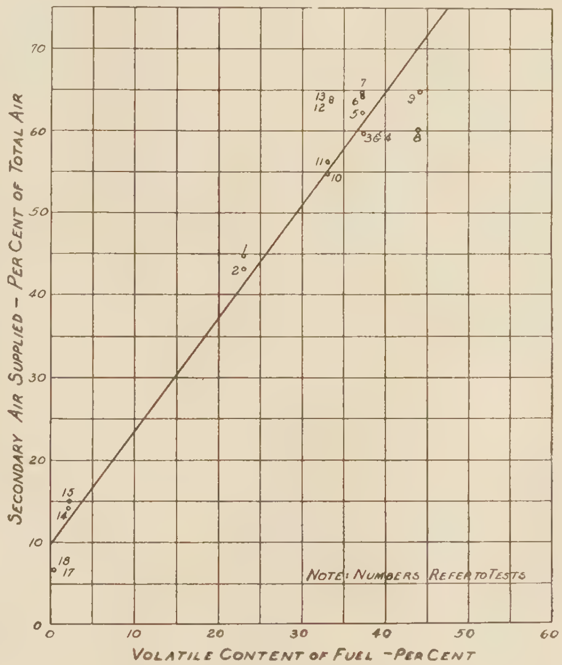

FIG. 6 RELATION OF VOLATILE CONTENT TO SECONDARY AIR

accurate sizing of coal is not essential for smokeless operation of this furnace.

Air Distribution. In order to obtain smokeless combustion, it was found necessary to supply from 55 to 65 per cent of the total air as secondary air for most Midwest bituminous coals. The relationship of volatile content to secondary air required is shown in Fig. 6.

A comparison of the orifices, selected by trial and error for each fuel, showed that practically the same combination was satisfactory for all bituminous coals having a volatile content of 30 to 40 per cent. The combination of orifices which would be suitable for practically all high-volatile bituminous coals was 2 in., 1 in., and 1 in. diam, respectively, for the secondary, coking, and undergrate air. This corresponds to an area relationship of 4 to 1 to 1, or on a percentage basis of 66.6, 16.6, and 16.6 per cent, respectively.

For a given temperature, and very small pressure drop across the orifice, the flow of atmospheric air may be expressed by the equation

$$W = KA(i)^{1/2}$$

in which
W = air flow, lb per sec
A = area of orifice, sq ft
K = constant
i = pressure drop across orifice, in. of water

[7] Data from which this graph was made were obtained during tests made in August, 1939, while burning Franklin County, Illinois, coal in this same furnace.

From this equation, it is evident that orifice area is the major factor in determining the rate of air flow through the orifice. Since i is ordinarily less than 0.1 in. of water, the change in $(i)^{1/2}$ for a small change in draft is almost negligible. Thus, orifice size is the controlling factor in determining air flow to the several chambers, regardless of minor changes in the resistance of either fuel bed. Otherwise, burning would not be stable, but would accelerate or decelerate in either fuel chamber as the resistance of the respective fuel beds decreased or increased. This effect is shown in the graphical logs by the reasonably steady air flow to each compartment during the whole of each firing cycle.

Combustion Efficiency. The CO_2 content of the stack gases averaged 10.46 per cent for all tests with a complete absence of CO. This represents approximately 70 per cent excess air. During the period of maximum volatilization, the excess air averaged 30.6 per cent. The loss of combustible in the refuse was high because of a loose-fitting shaking grate and thorough cleaning of the fire between tests. No difficulty was encountered on any test as the result of clinker formation.

Frequency of Firing. The average firing period for coal (not including wood or coke) during the high-rate tests was 4 hr, and during the low-rate tests was 8.32 hr. For the "banking" test, the interval was 12 hr. This indicates relatively less attention than that necessary for conventional updraft units. The fact that this furnace will operate smokelessly at low combustion rates indicates the possibility of increasing the fuel capacity and, consequently, of decreasing the frequency of firing.

Summary of Results Attained

The following general statements can be made concerning the furnace and the results of the tests:

1 High-volatile bituminous coal was burned without the formation of smoke.

2 Temperatures in the baffle wall were directly proportional to, and could be controlled by limiting, the amount of air admitted to the coking chamber.

3 Reasonable combustion efficiency was obtained during all tests as indicated by an average CO_2 content, ranging from 8.85 to 14.13 per cent, with complete absence of CO.

4 The amount of secondary air necessary for smokeless operation varied directly with the volatile content of the coal.

5 Secondary-air requirements of from 55 to 65 per cent of the total air supplied were necessary when burning high-volatile coal smokelessly.

6 The furnace successfully burned bituminous coal, coke, wood, sawdust, and anthracite.

7 The furnace responded quickly and smokelessly when fired after high-rate, low-rate, or banking operations.

8 No difficulties were encountered from the formation of clinkers or in pushing coke from the coking chamber to the coke-burning chamber. The comparatively hard coke from certain coals was partially broken up with a short bar before using the ordinary poker for pushing it into the coke-burning chamber.

9 The draft requirements are not above those normally obtained from a typical domestic chimney.

10 No difficulties were encountered in maintaining draft with any fuel tested.

11 Coal ranging in size from screenings to 2 × 3-in. nut was successfully burned.

12 The fuel-burning rate, using bituminous coal, was comparable to that for an updraft furnace of the same physical dimensions. The maximum burning rate was 8.89 lb per hr during these tests.

13 One combination of orifices was found to be satisfactory for all rates of combustion of any given fuel.

14 One combination of orifices would be satisfactory for all Midwestern bituminous coals.

15 The results indicate that this method of burning bituminous coal may be applied to all types of hand-fired equipment such as stoves, furnaces, boilers, and water heaters.

Discussion

W. G. Christy.[8] The authors are to be congratulated for their experimental work in a field where more engineering work should be done. There is need for equipment which will burn, smokelessly, potentially smoky fuels such as high-volatile bituminous coal.

The writer would like to call attention to two requirements upon which the success of the equipment depends:

The cost should be very little higher than competitive equipment. Users will not pay very much additional for smokeless equipment. It would appear that the furnace described in this paper will qualify in this respect. Quantity production should make the price reasonable.

Such equipment should be as near foolproof as possible. It has been demonstrated that many people do the wrong things and pay little attention to firing instructions. While this furnace is not complicated, it is a radical departure from the usual type of hand-fired furnace. In order that the furnace may function properly, coked coal must be pushed back. With such furnaces installed in homes, some people might fire additional fresh coal without pushing back the coked coal, or they may push the coal back before it is fully coked. In the latter case considerable smoke will likely result.

This furnace is an ingenious device. If operated according to instructions, it should be successful, economical, and smokeless. It is very desirable that some manufacturer build 50 or 100 of these furnaces and get them installed in districts where high-volatile bituminous coal is the prevailing domestic fuel. It will be interesting to observe how they perform in the hands of the public.

A. S. Langsdorf.[9] In a previous paper,[10] V. J. Azbe described a furnace equipped with a baffle designed to utilize the same downdraft principle that has been used by the authors. There is no doubt that the principle is sound and that furnaces constructed along these lines will be effective in preventing smoke, provided the material of which the baffle is made will stand up under the punishment it must take. In experiments made in St. Louis, an attempt was made to install baffles, some of them made of a chrome-steel alloy, in standard types of furnaces made by different manufacturers. Difficulty was experienced in providing satisfactory means for attaching the baffles to the furnaces which had not been designed to accommodate them. Better results may be expected if the furnace is originally designed to be fitted with a baffle, and studies of the kind reported in the paper under discussion are to be encouraged, particularly if they lead to the commercial introduction of small domestic furnaces which embody sound engineering principles.

There is one feature of the design shown in the illustrations which should receive more attention than is usually accorded to it. It is to be noted that the air inlets to the furnace are simple openings in the stove casing, a characteristic shared by all other

[8] Smoke Abatement Engineer, in charge of Hudson County Department of Smoke Regulation, Jersey City, N. J. Mem. A.S.M.E.

[9] Dean, Schools of Engineering and Architecture, Washington University, St. Louis, Mo. Mem. A.S.M.E.

[10] "Smokeless and Efficient Firing of Domestic Furnaces," by V. J. Azbe, Trans. A.S.M.E., vol. 49-50, 1927-1928, paper FSP-50-23, pp. 175–182.

types which have come to the writer's attention. It appears to be taken for granted that the air required to support combustion will somehow find its way into the air-inlet openings; but in cold weather, when the stove is really needed, it is the common practice of householders to shut all doors and windows of the room in which the stove is installed, so that the air supply is restricted to the inadequate amount that leaks through the window sashes and door frames. Every stove manufacturer should be compelled to provide a positive source of air in the same way that he is obliged to provide a vent for the products of combustion. Conduits or ducts for air supply should be as much an integral part of the installation as is the smoke pipe.

Eugene Murphy.[11] Several questions on the application of this interesting new furnace occur to the writer. The authors state that relatively less attention will be required than that necessary for conventional updraft units. During typical weather in the region for which the furnace is designed, may a householder tend the furnace only in the morning and evening?

Will the average adult be able to operate the furnace properly without special skill or training?

Clearly the furnace shown was constructed as an experimental model. Have the authors attempted to remodel a commercially available furnace or to estimate costs of commercially constructed furnaces built to operate on the same fundamental principle?

Authors' Closure

The authors desire to thank Mr. Christy, Dean Langsdorf, and Mr. Murphy for their interesting comments.

In answer to Mr. Christy's question, concerning the proper operation of the furnace, the authors do not believe that it will be difficult to educate the public to use this type of furnace properly. The fire does not respond after the coke has burned out of the coke-burning chamber, and adding fresh fuel will not result in the production of an appreciable amount of heat unless the coke from the previous charge is first broken up and pushed into the coke-burning chamber. In other words, the authors feel that proper operation of the furnace is necessary to obtain satisfactory heating, and that smokeless combustion will result even though the operator is not particularly interested in smoke elimination.

In reply to Mr. Christy's suggestion, the authors are happy to report that a reliable furnace manufacturer is now working on a commercial design of this furnace to be placed on the market in the near future.

The authors recognize the need for positive air supply to any furnace, as pointed out by Dean Langsdorf. However, the need would not be as critical with this type of stove or furnace as with the conventional types, because periods of high rates of volatilization are eliminated and, consequently, the maximum air requirements are much lower for the same average combustion rate.

In answer to Mr. Murphy's first question, the authors wish to state that they believe furnaces of this type, if properly proportioned to the heat load, will perform satisfactorily during typical Illinois weather, if given attention only morning and evening.

The authors do not believe there is any question about the ability of the average person to operate the furnace. The only step in the firing procedure that is different from that used in firing any furnace is that of pushing the coke down before refiring. The shape of the coking chamber makes this operation much simpler than that of pushing coke to the back or side of the firepot of the conventional furnace.

The "downdraft conversion burner" for converting the conventional updraft furnace to this same downdraft principle of operation has been tried out in approximately 20 different homes, and has been operated by all types of people, with no difficulty in their learning to operate it satisfactorily.

Some Problems in Pulverizing and Burning Midwest Coals

By A. C. Foster,[1] New York, N. Y.

The author cites the characteristics of Midwest coals which require special consideration in the design of pulverizers and boiler furnaces to meet the conditions of combustion. The principal items to be provided are (1) large furnace volume with moderate heat-release rates, (2) ample furnace cooling surface, (3) preheated air at sufficient temperature to enable pulverizer to pulverize coal with maximum moisture content which may be encountered, (4) ample mill capacity. The paper includes a discussion of these various elements in the solution of the problem of burning Midwest coals efficiently.

The successful pulverizing and burning of low-grade Midwest coals in boiler furnaces requires that adequate provisions be made in the original design for the following coal characteristics:

1 Low ash-softening and fusion temperatures.
2 Negligible coking tendency.
3 Generally high moisture content.
4 Low to moderate grindability.

The first two characteristics determine the design of the furnace and the selection of burners; the third and fourth influence the choice of coal-preparation and pulverizing equipment.

Noncoking Midwest coals are free-burning and, even when quite coarsely pulverized, they burn easily and with a relatively low unburned-carbon loss. However, the ash slags easily and, for this reason alone, these coals are more troublesome than most of our native coals. This inherent slagging tendency is one factor requiring the designer's closest attention.

Today operators everywhere demand equipment that is capable of staying on the line for long periods of time. It is not uncommon to find operators scheduling boilers "on the line" for periods of 6 months, and being able to maintain these schedules. Obviously, such performance requires, in addition to freedom from mechanical breakdown, also freedom from fouling of the furnace, boiler, and superheater with slag and ash. The heat-absorbing surfaces and the gas passages between them must be kept clean. How then can we best obtain such cleanliness as will enable the operator to keep the unit "on the line" for long periods, when low-grade, low-ash-fusion coals must be burned?

It is possible to make provisions in the original design of a steam-generating unit for the removal of ash and slag from heat-absorbing surfaces by mechanical soot blowers and deslaggers and by designing with free access to all parts for hand lancing. However, experience indicates that even the most elaborate provisions of this kind will not offset violations of sound furnace design and firing principles. So, rather than depend alone upon such methods to prevent slagging, close attention should be given to those design factors, which, if followed, will give the operator complete control of the slag problem and a minimum of hand cleaning when burning these coals.

The principal design factors influencing the fouling of steam-generator heating surfaces by low-fusion-temperature ash or slag are as follows:

1 Furnace proportions.
2 Arrangement of furnace cooling surface.
3 Type of cooling surface.
4 Location of burners.
5 Disposition of heating surface before the superheater.
6 Arrangement of superheater.
7 Fineness of pulverization.

Furnace Proportions

The furnace should be designed for a moderate heat release. For Midwest coals, while this will be predicated on other conditions, such as ratio of cooling surface in furnace to furnace volume, whether dry-bottom or slagging-bottom type, and arrangement of burners with respect to boiler entrance or furnace exit, heat releases of the order of 21,000 to 25,000 Btu per hr per cu ft have been found desirable.

The cross section of the furnace should be such that the gas velocity, in the clear space between the flame and the entrance to the boiler-tube bank, will be low enough to permit the larger particles of fuel and ash to "hover" or move about more slowly than the gas, and so give the radiant-heat-absorbing surfaces a greater opportunity to cool and solidify even the largest particles before they can reach the furnace outlet. It is also desirable to have the area of the furnace outlet arranged to provide a low gas velocity entering the boiler bank in order to minimize the fouling which results when those globules of ash, which are frozen only on the surface but are still molten within, impinge on the boiler tubes.

It would be interesting to have available, from Midwest operators, additional data on the capitalized value of deslagging, and hand-lancing costs, plus necessary outages for cleaning, versus excess of furnace-exit-gas temperature over the ash-sticking temperature. If furnace-exit temperatures are not available the average heat liberation per square foot of effectively exposed radiant surface could serve as a basis for comparison of these costs. It is believed that such a survey will tend to justify extremely conservative furnaces.

Arrangement of Furnace Cooling Surface

Many arrangements of furnace cooling surface are possible. With any of them the gases should be cooled sufficiently and the particles of ash in suspension chilled and solidified before they reach the furnace outlet or boiler entrance.

It is desirable that combustion be completed in minimum time and space and this may be accomplished by the use of turbulent burners which promote rapid and intimate mixing of the coal and air. With a short turbulent flame we obtain the maximum of clear atmosphere in the furnace, both from above the flame body to the gas outlet and from below the flame body to the floor or ash hopper, to effect the ready cooling of ash particles by radiation to the surrounding surfaces.

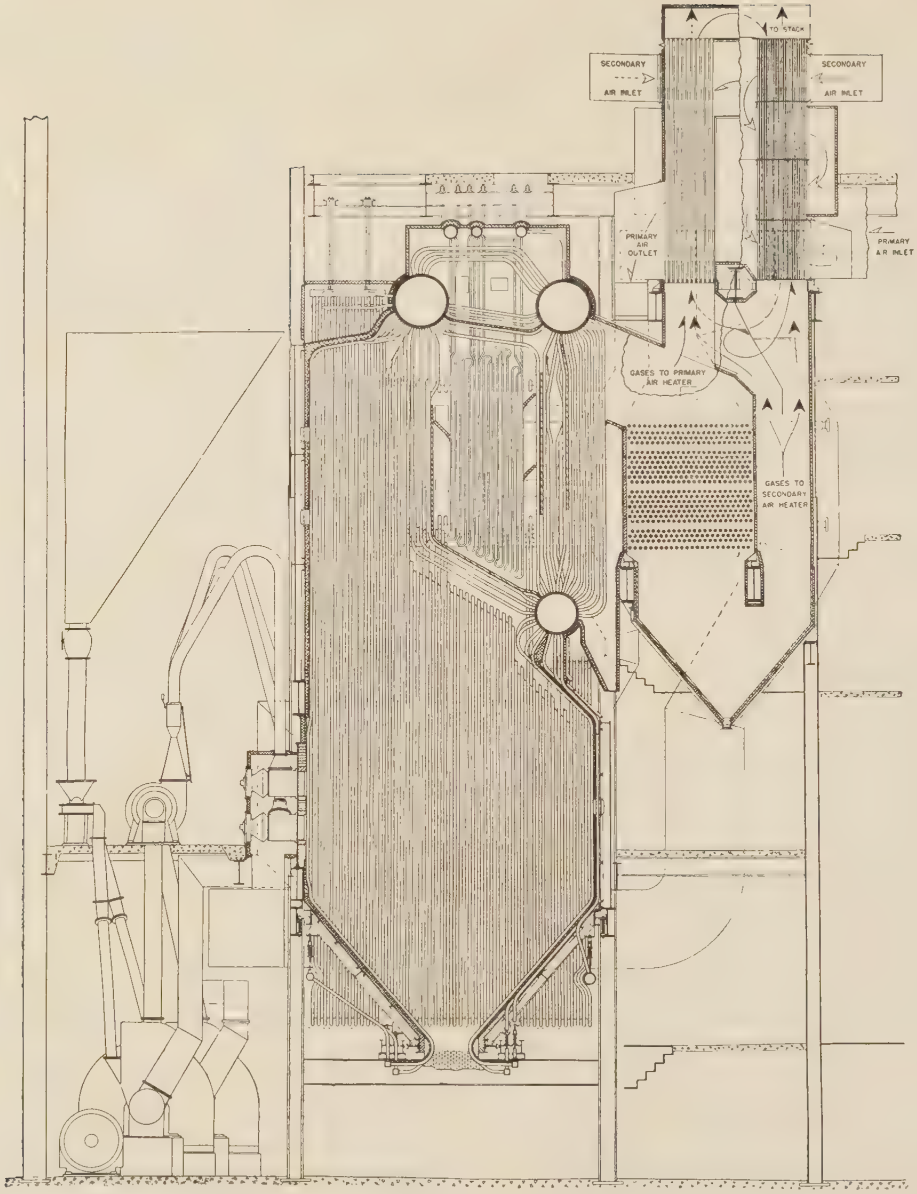

Fig. 1 Conventionally Designed Unit for an Output of 550,000 Lb per Hr at 870 Psi and 900 F With 300 F Feedwater

The highest gas temperatures prevail in that part of the furnace adjacent to the burners. It has been our experience that the most effective cooling surface should be available in this region to take full advantage of the high rates of heat absorption and corresponding rapid rates of ash cooling which are attainable in this zone. Any covering of cooling surface adjacent to the burners tends to restrict its effectiveness and defeat one of the purposes for which it was primarily installed. Bare tubes provide the most rapid heat-absorbing surface and are used even in this region. There need be no concern regarding blistering and tube failures if there is adequate circulation, freedom from violent flame impingement on the outer surface of the tubes, and the absence of scale or oil on the inner surface.

Of the various types of furnace cooling surface in use today, bare tangent tubes, that is, bare tubes so closely spaced as to leave very little space between them, provide the most effective cooling and the least furnace-wall slagging. This is due to the absence of anchorages, or high-temperature zones, between the tubes to which ash and slag may bond to form a continuous covering over the tubes.

Location of Burners

The most desirable location of burners will depend upon whether the furnace is of the dry-bottom or the slagging type. Too often the burner location is subordinated to some predetermined or existing arrangement of auxiliary equipment such as a stack, ash-handling equipment, coal bunker, etc.

In furnaces of the dry-bottom type, burners should be located high enough above the floor, or ash hopper, to assure cooling of the ash below the "sticky" temperature before it comes in contact with the cooler surfaces below the burners.

In furnaces of the slagging type, burners firing horizontally

near the slag floor and arranged to distribute the fuel evenly across the full width of the furnace have given excellent results. In this way a blanket of flame is interposed between the slag and the furnace cooling surface above the flame. The slag floor is thus maintained at a high temperature, because it cannot "see" the cooling areas through the flame. Where multiple burners are used it is extremely important that the coal be evenly distributed across the width of the furnace to avoid stratified zones of high temperature and accompanying spotty slag accumulations throughout the unit.

Assuming conventional types of steam generators, having the boiler located above a furnace of either dry-bottom or slagging type, the preferred direction of firing has been found to be away from the entrance to the boiler-tube bank, which usually means that the burners are set in the wall directly below the bottom drum. Such an arrangement insures minimum slagging of the boiler entrance.

Slag screens and boiler heating surface before the superheater, if arranged vertically, tend to be self-cleaning and give least trouble from slagging. The tubes should be spaced wide enough

apart to prevent bridging across of such ash or slag as might stick to them.

Arrangement of Superheater

Superheater tubes give least trouble if arranged vertically as in the pendent, self-supporting superheater, in which the elements hang from external headers. This type of superheater promotes external cleanliness and inhibits fouling by slag and fly ash, due to the absence of large supports and hangers within the gas path. Attempts to economize in superheater surface, by designing for high gas-mass flow, with closely packed tubes, invite troublesome slagging. Such installations run the risk of subsequent unsatisfactory operation.

Fig. 1 shows a conventionally designed unit in which the designer has endeavored to follow these principles.

Fig. 2 shows a twin-furnace unit designed for about the same output. This design permits maximum cooling of the furnace gases because of the greater ratio of furnace cooling surface to furnace volume than is found in the conventional design. The arrangement of superheater surface in radiant and convection sections, with the radiant section in what is in reality a separately fired furnace, enables the maintenance of the maximum final steam temperature over an extremely wide range, with low gas temperature entering the convection superheater. This is accomplished with approximately two thirds of the superheater surface that would be required in a conventionally designed unit with an all-convection superheater.

Fineness of Pulverization

Throughout the history of pulverized-coal firing in steam-

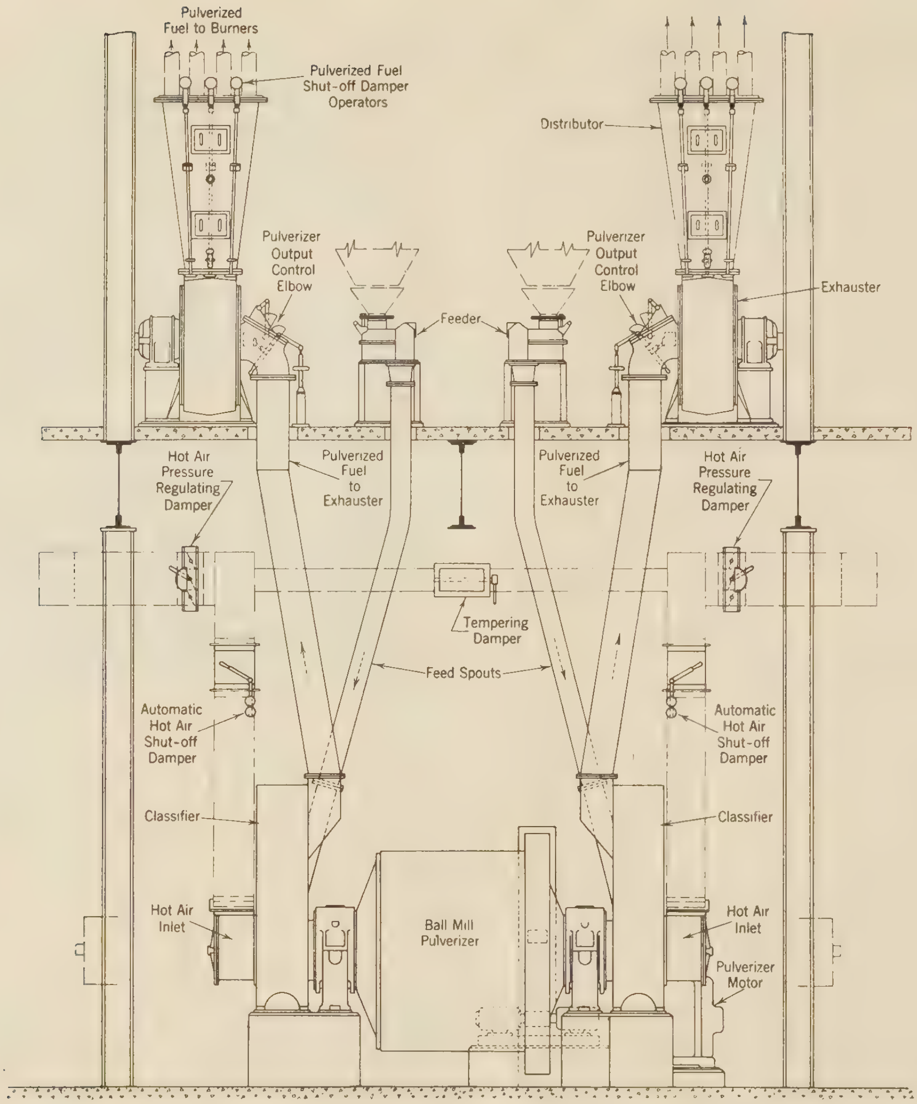

Fig. 4 Double-Classifier Mill With Twin Exhausters and Twin Feeders

generating units coarse pulverization and boiler-entrance slagging have gone hand in hand. The effect of fine grinding on both combustible loss and slagging of the boiler entrance and superheater is more noticeable with the low-grade, low-ash-fusion-temperature coals than with the better coals. The smaller the particle the more certain it is to be cooled throughout by the time it passes into the boiler and superheater. Likewise, since the loss due to unburned combustible is reduced by finer grinding, it means that we have fewer particles reaching the boiler and superheater while still burning.

There are, of course, economical limits beyond which finer grinding may not pay dividends. These limits are not always easily defined. Finer grinding increases power consumption. In addition to the savings resulting from decreased carbon loss there are the more or less intangible savings resulting from the reduction in cleaning labor, steam, etc., the improvement in net over-all efficiency due to reduction in soot-blower operation, and time for hand lancing. The value of the reduced outage time for cleaning and the resulting increase in availability may be worth more than all of these savings put together. This is something that can only be determined by each individual plant.

The free-burning Midwest coals may easily be burned with a carbon loss of less than 1 per cent, with a fineness of about 70 per cent through 200 mesh. Nevertheless, experience has indicated that the fineness may advantageously be as high as 80 to 85 per cent through 200 mesh, in order to minimize boiler and superheater fouling.

The third and fourth characteristics affecting the successful pulverizing and burning of low-grade Midwest coals, namely, high moisture content and low to moderate grindability, as previously pointed out, influence the choice of coal preparation and pulverizing equipment.

Specifications for pulverizers to handle Midwest coals usually require that the pulverizer be capable of handling coal of 13 to 15 per cent moisture. In all probability the moisture specified is the average moisture over some period of time. It may happen that when the installation is placed in operation the total moisture content is greater than specified. We have had occasions where

it has been necessary to pulverize Midwest coals containing 19 to 20 per cent moisture. The conical ball mill will satisfactorily handle coals of this moisture content and even higher, providing preheated air at a high enough temperature is available.

Fig. 3 shows a double-classifier ball mill equipped with a single exhauster and a single feeder arranged to feed and remove the coal from both ends of the mill.

Preheated air, preferably at temperatures of 500 to 600 F, is admitted through pipes centrally located in the hollow trunnions at each end and the pulverized fuel is carried out through the annular openings between the hollow trunnions and the central pipes into the classifiers at each end of the mill. The finished product leaves the classifiers through two conduits which are, in this case, brought together at a Y connection and connected to the exhauster through the output-control elbow.

This arrangement of classifiers provides a large recirculating load. At times the rejected material being returned to the mill, from the classifiers, may amount to three or four times the quantity of coal being delivered to the exhausters. The raw incoming coal is fed in approximately equal amounts to each classifier. Here it is mixed with the partially dry and semipulverized rejects and fed into the mill by the double-flight ribbon conveyers which

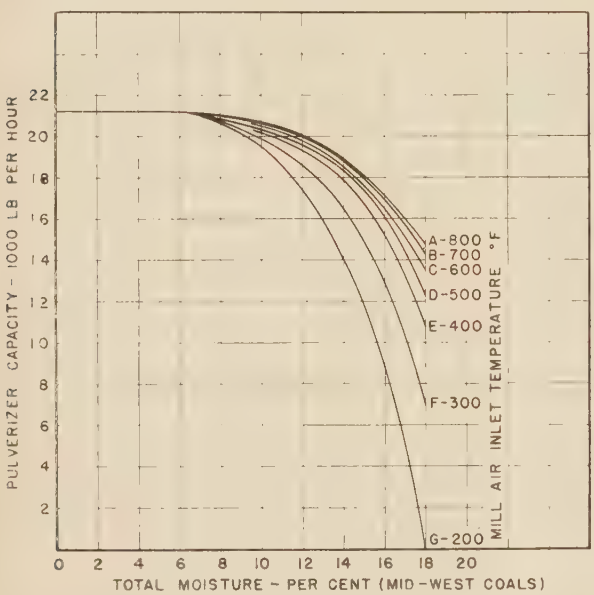

Fig. 5 Effect of Initial Moisture Content on Pulverizer Capacity With Varying Mill Air-Inlet Temperature

are attached to the rotating air-inlet tube. This air-inlet tube is driven by the mill through a spider shown at the mill end of the tube.

Mixing the raw incoming feed with the warm dried classifier rejects reduces the effect of surface moisture on mill capacity for the following reasons:

1 Part of the surface moisture is transferred to the warm rejects. Preliminary warming of the incoming wet coal takes place in the classifier; some drying takes place during the time required to convey the coal from the classifier to the mill. Thus, if the raw coal fed to the classifier contains a total of 15 to 20 per cent moisture, corresponding to a surface-moisture content of 8 to 13 per cent, the mixture of raw coal and rejects entering the mill from the classifier will have an average surface-moisture content of 2 to 4 per cent. This corresponds to an average total moisture content of 9 to 11 per cent, which is appreciably less than 15 to 20 per cent.

2 In transferring part of the surface moisture of the incoming coal to the warm semipulverized rejects, the moisture is transferred to a much larger and warmer surface area, from which it is more easily evaporated.

Fig. 4 shows a double-classifier mill, arranged with two exhausters and two feeders, with each feeder and each exhauster serving one classifier.

The question frequently arises as to how more grinding capacity can be obtained from mills which may be handling poorer grades of coal than was anticipated at the time they were purchased. Let us first consider the possibility that mill output is limited because the moisture of the incoming coal is higher than was anticipated. An increase in the temperature of the preheated air to the mill will improve the mill performance.

If the air temperature is below 300 F the installation of a steam air heater to increase the temperature to somewhere in the neighborhood of 400 F is possible, provided steam at a pressure of 350 to 400 psi is available. Such an air heater can usually be installed in the air ducts supplying preheated air to the mill.

Another method is to install a special primary-air-heater section on the gas side of the steam-generating unit. This should be arranged so that the partially preheated primary air from the outlet of the secondary-air preheater enters the primary-air heater to be further heated by gases taken from a higher-temperature region than those normally entering the secondary-air heater. This makes it possible to increase the primary-air temperature to 500 or 600 F, depending upon the gas temperature available. The unit, shown in Fig. 1, is equipped with such a primary-air heater. The lines having only one half an arrow head indicate the flow of gas and air through the primary-air-heater section, which is centrally located with twin secondary-air heaters on each side of it.

It may prove advantageous to increase the temperature of the air going to the mill by mixing with the air a small amount of flue gas taken from a section of the boiler where the gas temperature is in the neighborhood of 1000 to 1200 F. Only a limited amount of flue gas can be mixed with the primary air. This quantity will depend upon the volatile and ash content of the fuel being burned, and for Midwest coals will be about 20 per cent by weight. An excessive amount of flue gas added to the primary air may decrease the burner stability because of the inert gas present.

There is a limit to the improvement which may be expected from an increase in temperature of the air entering the mill. The law of diminishing returns sets a temperature of 600 to 650 F as the practical upper limit. This is shown in Fig. 5, where a series of curves indicates the effect of raw-coal moisture content on mill capacity with varying air temperatures entering the mill.

If we consider a pulverizer, selected for a capacity of 18,600 lb per hr with a total moisture content of 12 per cent and an air temperature to the mill of 300 F, it will be seen that an increase in raw-coal moisture content to 16 per cent will reduce the mill output to about 13,000 lb per hr. However, if an entering-air temperature of 600 F is available, the output will only be reduced to 16,500 lb per hr. Increasing the inlet-air temperature from 600 to 800 F will only increase the output, with 16 per cent moisture coal, from 16,500 to 17,100 lb per hr, a negligible amount. This same pulverizer will have the same capacity with 14 per cent moisture raw coal and 600 F entering air as it has with 12 per cent moisture and 300 F entering air. The effect of increased air temperatures diminishes with decreasing raw-coal moisture content.

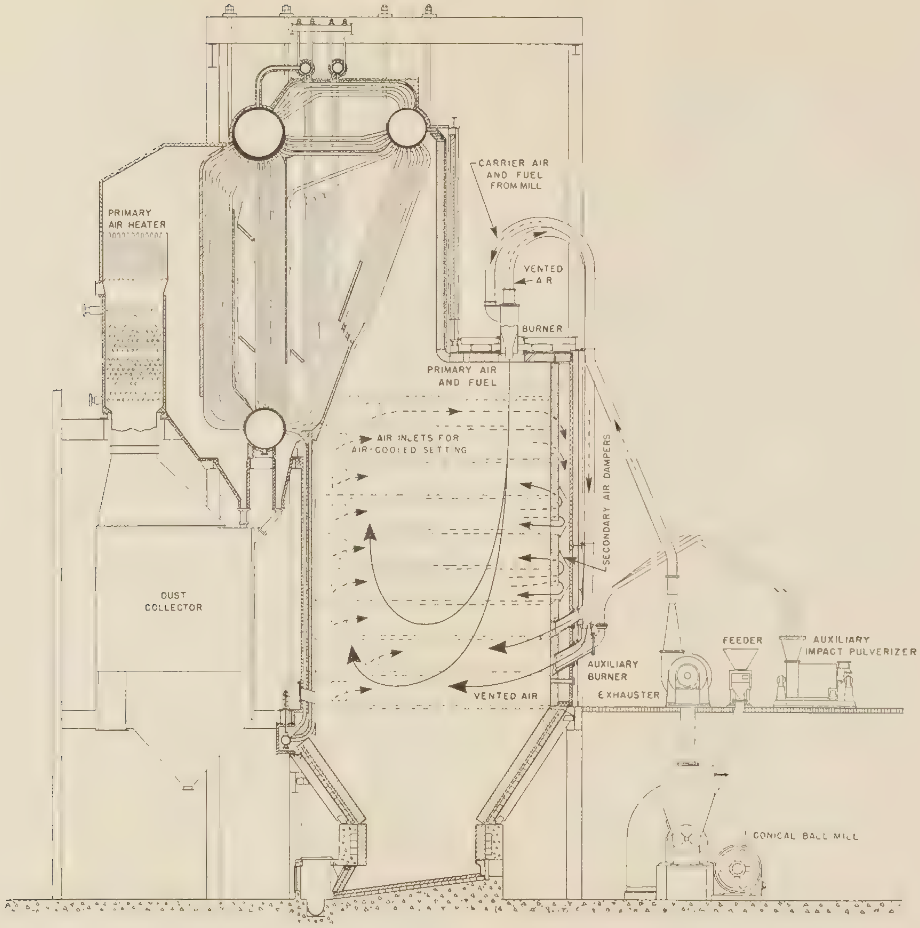

Fig. 6 Unit Having Separate High-Temperature Plate-Type Primary-Air Heater for Coal Containing up to 20 Per Cent Moisture

Fig. 6 shows a unit equipped with a separate plate-type heater which may be used with or without a secondary-air heater. Similar installations of horizontal-tubular type have also been made. Whether used singly or in conjunction with a secondary-air heater, this type of installation can be installed to give a primary-air temperature of 500 to 600 F, providing flue gas in the neighborhood of 900 F is available.

Most operators have seen occasions when it has been necessary to operate with water running from the raw-coal bunkers through the scales, feeders, and raw-coal conduits into the mill. These have been, of course, extraordinary conditions. Fig. 7 shows a simple arrangement that can be installed in any coal bunker to eliminate this condition. It consists of a short addition to the coal pipe, extending up into the bunker in such a manner that a trough is formed between this extension and the sides of the bunker. Suitable drain connections are provided to drain off the excess surface moisture, which will collect in the trough. In plants where coal takes fire easily in the bunker, if not kept moving, the dead space between the extension and the side of the bunker may be filled with crushed rock as shown. This will also reduce the necessity for cleaning out the drain lines. This device has been used in numerous plants, particularly in Canada, where large quantities of snow and ice find their way into the coal bunker during the winter. If, in connection with this moisture trap in the bunker, sufficient bunker capacity is available so that provisions can be made to allow the incoming coal

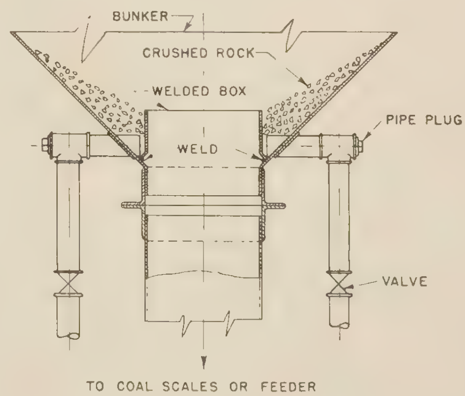

Fig. 7 Arrangement to Prevent Run-Off Water Entering Pulverizer

to remain in a section of the bunker for a period of 24 hours before it is fed to the mill, an appreciable reduction in the surface moisture content of the raw coal can be expected.

If it becomes necessary to grind harder coal a reduction in mill capacity must be expected, unless additional power for pulverizing is provided, or a reduction in fineness accepted. An increase in grinding capacity may be obtained, in the case of a

ball mill, by increasing the weight of the ball charge and by increasing the percentage of larger-diameter balls in the charge. In other types of mills this may involve an increase in the loading pressure on the grinding elements or an increase in speed.

All of these steps usually result in an increase in the power required for the mill motor. In cases where changes of this nature may be limited, because of such conditions as the mill motors' being fully loaded, or the motor circuits' being fully loaded, some improvement in mill capacity can be expected from crushing the incoming coal to smaller sizes.

The pulverizing and burning of low-grade Midwest coals offer problems not usually associated with the higher-grade Eastern coals. It is the designer's responsibility to recognize the important characteristics affecting the successful burning and pulverizing of these coals and provide:

1 Large furnace volume with moderate heat-release rates.

2 Ample cooling surface in the furnace.

3 Preheated air at sufficient temperature to enable the pulverizer to pulverize coal with the maximum moisture content that may be experienced.

4 Ample mill capacity to provide fine grinding with the worst coals likely to be encountered.

If these conditions are satisfied there should be no serious problems for the operators to overcome.

Discussion

Ray Winters.[2] It would seem that the information requested by the author on the cost of slagging with furnace-exit temperature above the ash-sticking temperature is a matter of checking past records. When pulverized coal was first used under steam boilers, most furnaces were too small and employed only refractory lining, which gave high gas temperatures. Generally lower ratings and additional excess air were resorted to rather than have continuous slagging conditions which required constant cleaning. When operating under such conditions, there is always the possibility of slag reducing the rating or shutting the boiler down.

[2] Results Engineer, Kansas City Power & Light Co., Kansas City, Mo.

If furnaces are designed to maintain gas temperatures below the sticking point, two men working 1 hour per shift or 6 man-hr per day will keep a 200,000 to 300,000-lb boiler clean. With the temperature above the sticking point, 48 or more man-hr would be required. At 80 cents per hour and 85 per cent service, the slagging would cost $10,250. The labor cost alone would justify an additional furnace cost of over $85,000. Therefore, it seems that furnaces should be designed to give furnace-exit temperatures with a generous margin under the ash-sticking temperature.

Increasing fineness of the coal not only reduces slagging but reduces the unburned-carbon loss. At Northeast Station the loss decreased from 0.69 per cent to 0.36 per cent by increasing the fineness through 200 mesh from 54 per cent to 71 per cent.

The author's discussion of the effect of moisture on mill capacity and power requirements should prevent the future installation of undersized units, as has occurred many times in the past.

Author's Closure

It is indeed gratifying to receive the data on boiler cleaning costs contained in Mr. Winters' discussion. The cost of boiler cleaning, particularly when such cleaning requires hand lancing in addition to regular mechanical soot-blower operation, is a phase of boiler operation and operation costs that sometimes is not even considered and too frequently is not given sufficient consideration in evaluating one type or size of steam-generating unit against another. As pointed out by Mr. Winters, removal of slag from boiler and superheater surface requires a considerable expenditure for labor and, therefore, a considerably higher capital investment may be justified for a unit designed to provide furnace-exit gas temperatures below the ash-sticking temperature.

The figures given for the decrease in carbon loss resulting from increased fineness confirm the author's findings in other installations. They are particularly interesting inasmuch as they show that, even with free-burning Midwestern coals that have relatively low combustible loss even when quite coarsely pulverized, a worthwhile improvement in efficiency can be obtained by pulverizing finer. With less-free-burning coals the effect of increased fineness on reduction in combustible loss will be even greater.

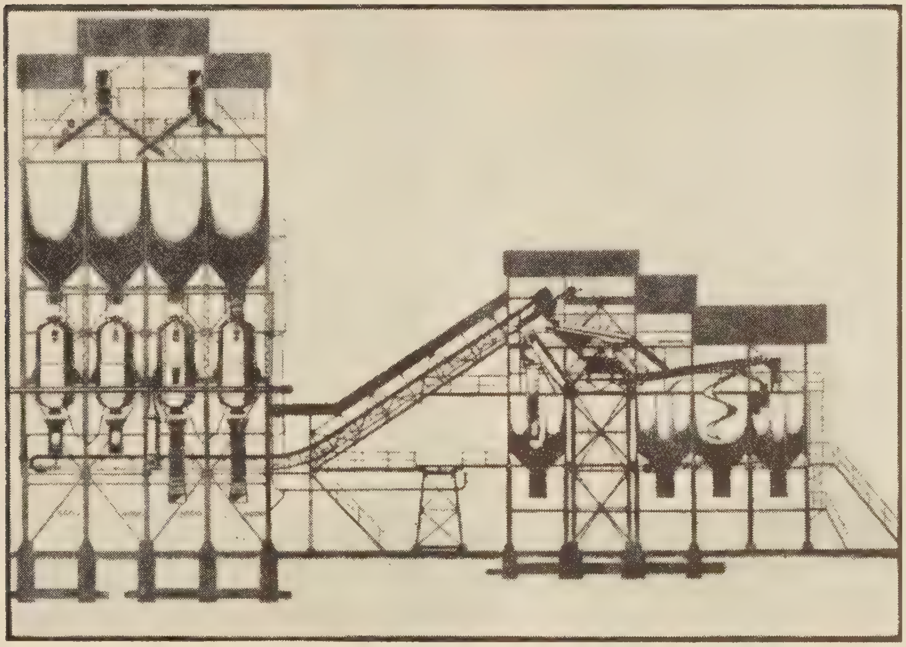

FIG. 1 LONGITUDINAL SECTION, KOEFLACH PLANT

The Preparation of Stable Nonslacking Fuel by Steam-Drying Subbituminous Coal and Lignite[1]

BY V. F. PARRY,[2] L. C. HARRINGTON,[3] AND ARTHUR KOTH[4]

Subbituminous coal and lignite, as mined, contain 20 to 40 per cent moisture, which limits their markets, due to slacking and to the costs of transporting this water. By drying these fuels with saturated steam at 400 psi pressure, by the Fleissner process, described in this paper, the free-moisture content may be lowered to 4 to 8 per cent, reducing slacking and increasing the available market. The properties of the dried fuel and processing data are presented and the construction and operating costs of plants are estimated.

ENLARGEMENT of the markets for the lower-rank coals is in accord with a thoughtful national policy on conservation of energy, which recommends that the lower-rank fuels should be used for generating power and heat where economically possible to conserve the highest-rank coking coals and oil or gas, which have a more limited reserve (1).[5] The subbituminous coals and lignites of the eastern slope of the Rocky Mountains and the Northern Great Plains area represent two fifths of all coal reserves of the United States but, owing to the distance and to the cost of transporting the moisture in the coal, these fuels have limited markets. In a normal year the production in this area averages about 3 per cent of the national output of coal. North Dakota alone has an estimated reserve of 600,000,000,000 tons of lignite, but its yearly production of 2,000,000 tons is consumed largely within the state. The economical boundary for shipments of lignite, owing to the weight of its high moisture content, is about 50 miles east of the state line and 100 to 200 miles into South Dakota. Beyond these points, lignite must compete with coals shipped through the Great Lakes from West Virginia and Kentucky; therefore, if the markets for lignite are to be enlarged, methods must be found to decrease the moisture at the mine. This paper summarizes some of the studies which have been made by the University of North Dakota, in co-operation with the Bureau of Mines, United States Department of the Interior, on improving subbituminous coal and lignite by drying with steam.

Contributed by the Fuels Division and presented at the Semi-Annual Meeting, Kansas City, Mo., June 16–19, 1941, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

The object of the investigation was to determine the economic possibilities of applying the Fleissner steam-drying process to American coals.

Fleissner Steam-Drying Process

Lignite has been dried successfully in Europe for 13 years, and three plants having a total capacity of about 2000 tons daily are now in operation in the countries recently known as Austria, Czechoslovakia, and Hungary (2). A typical commercial plant is shown in Fig. 1. The steam-drying process involves heating

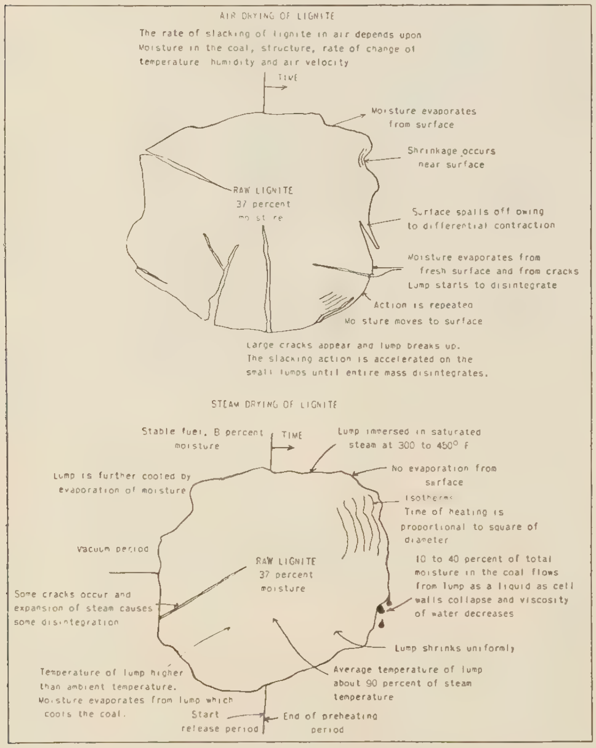

Fig. 2 Air Drying of Lignite and Steam Drying of Lignite

raw lignite with saturated steam until the lumps are heated to the center; the pressure is then released, and a vacuum is applied which cools the coal through evaporation of moisture.[6] When the lumps are heated with saturated steam no water can evaporate at the surface, consequently slacking does not take place as it does in atmospheric drying. It has been demonstrated experimentally that part of the natural bed moisture is forced from the coal as a liquid under the conditions imposed by heating with saturated steam. Owing to this effect, the thermal requirements for steam drying are less than for flue-gas drying because no latent heat of evaporation is necessary to remove the liquid water. Heating with saturated steam also affects the structure of the coal, either by collapsing the cells or by closing the capillaries. As a result, the dried lignites do not absorb water as readily, the slacking properties are reduced, and the fuels are more stable when exposed to the atmosphere. Fig. 2 is a schematic description of the sequence of events when a lump of lignite is dried in air and in saturated steam.

The action of high-pressure saturated steam on a lump of lignite produces the following effects: The lump is heated uniformly by its envelope of condensing steam. As the pressure increases and the temperature rises, part of the colloidal water is expelled from the lump as a liquid. The lump shrinks as water leaves and when the pressure is lowered more water evaporates owing to the sensible heat stored in the lump. When the pressure is lowered further by vacuum, additional moisture is evaporated, which cools the lignite to about 140 F. The apparent density of lignite is decreased about 20 per cent by drying.

EXPERIMENTAL WORK AT NORTH DAKOTA UNIVERSITY

Description of Pilot Plant and Tests

Experimental investigations of the application of the Fleissner steam-drying process to American coals and lignites had been made by the University of North Dakota, before the present investigation in co-operation with the Federal Bureau of Mines (3). The results of that work indicated that the process should be technically successful on American lignites.

The experimental work described in this paper was conducted in a small pilot plant having a capacity of 1 ton of coal per day. The plant is shown in Fig. 3. About 50 tons of raw lignite were dried under a variety of conditions to furnish data for a technical and economic appraisal of the process. Two series of tests were made to obtain comparable information on several coals. The first series was made on large samples of lignite from four mines in North Dakota and the second series on small samples of sub-

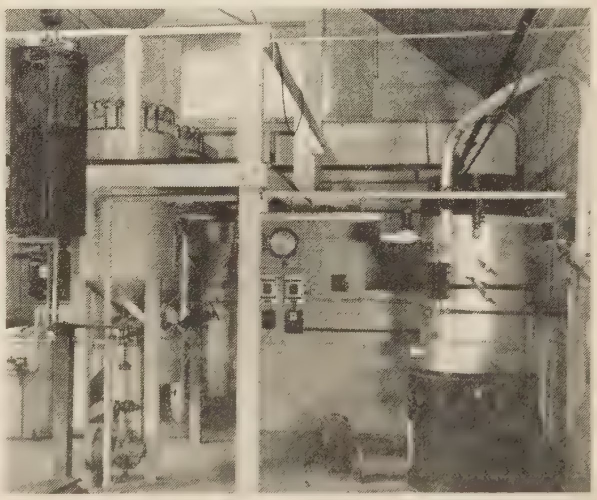

Fig. 3 Experimental Drying Plant, University of North Dakota

---

[6] Two autoclaves are required for proper operation of the process. Steam from the high-pressure autoclave is expanded into the low-pressure autoclave to preheat the raw coal. The cycle on two autoclaves is timed as follows:

Let A = time required for equalizing pressure between the two autoclaves
B = steaming time, using fresh steam from boiler
C = time required to evacuate autoclave containing dried coal after pressure is equalized
D = time required to charge and discharge one autoclave

Then B must equal $C + D$; $A + B$ = heating period; and $A + C$ = cooling period.

A 42-min cycle would be timed as follows:

Elapsed time, min	No. 1 autoclave, min		No. 2 autoclave, min	
0				
8	8 Equalize pressure	(A)	8 Preheating	(A)
16	8 Evacuate	(C)		
21	5 Empty and charge vessel	(D)	13 Steaming with fresh steam	(B)
29	8 Preheating	(A)	8 Equalize pressure	(A)
37			8 Evacuate	(C)
42	13 Steaming	(B)	5 Empty and charge	(D)
50	8 Equalize pressure		8 Preheating	

bituminous coal and lignite from nine mines in North Dakota, Wyoming, and Colorado. The large samples were shipped to the plant in railroad boxcars and stored in burlap sacks in concrete storage bins where they remained until sent to the drying plant. After drying, the processed lignite was stored in sacks in an open frame building where it remained for several months awaiting additional tests. The small samples were delivered to the drying plant in sealed drums and kept in the drums until dried. This precaution eliminated the questionable effects of open storage in concrete bins, and results showed that fresh lignite dries better than older lignite.

The effects of steam pressure, length of heating time, steam consumption, and size of lumps were studied. Most of the experimental work on the large samples was conducted in cycles aggregating about 140 min. The processing time was divided into a preheating period, a heating period, and a release period, followed by vacuum and aeration to cool the coal. European practice had defined these periods as definite parts of the process, but as more experience was obtained on processing the several lignites in the pilot plant, it was observed that steam drying can be considered best by dividing the processing time into only two periods, a heating period and a cooling period.[7] During the heating period, the temperature of the ambient steam is higher than that of the lumps, and the steam pressure is rising. The source of steam may be either from expansion from the previously heated autoclave or from a steam boiler. The length of the heating period depends upon the size of the lumps. When they have attained a temperature nearly equal to that corresponding to the maximum steam pressure, the heating period is complete and cooling can begin. Slight advantage is gained by extending the heating period beyond the time required to heat the lumps. Some liquid water is forced from the coal during heating. During the cooling period, the temperature of the coal is higher than the temperature of the ambient steam, and moisture evaporates constantly as the differential temperature is

maintained, either by dropping the steam pressure or by application of vacuum. The time required for this period has not been fully investigated. If the pressure were suddenly released to atmospheric, the potential energy within the lumps might be sufficient to explode the coal, similar to the effect produced in

[7] The heating period has been divided into two periods, the time required to raise the pressure to the maximum processing pressure and the time the lumps are allowed to "soak" at constant pressure while coming to temperature. The size of the lumps determines the relative length of these two parts of the heating period.

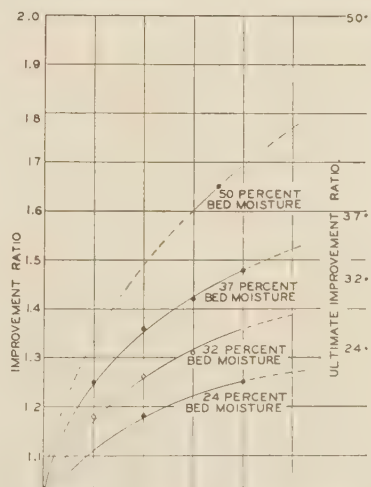

FIG. 6 RELATION BETWEEN STEAM PRESSURE, IMPROVEMENT RATIO, AND BED MOISTURE

making puffed rice. If the pressure is released gradually, this energy is restrained and fracturing probably is decreased. Experiments have shown that the cooling period can be less than 10 min on $1^1/_2$-in. coal.

Summary of Results

Table 1 shows the average properties of raw and dried lignite and raw and dried subbituminous coal before and after processing at 400 psi pressure. It should be noted that the ratio of corresponding weights of raw coal to dry coal virtually equals the ratios of their gross heating value, volatile matter, and fixed carbon. This ratio is arbitrarily called the "improvement ratio" to define the degree of improvement due to drying. The available-heat ratio is higher than the weight ratio owing to the greater losses of latent and sensible heat when raw coal is burned.

Fig. 4 shows the relationship of improvement ratio, heating value, weight, and moisture content of the dried coal as the steam pressure increases. These curves represent the average results on North Dakota lignite. Lignites respond differently to saturated steam because the structure, bed moisture, and proportions of earthy and peaty material influence the drying properties. The most noticeable variation is that of improvement ratio with respect to bed moisture and steam pressure. Fig. 5 illustrates this relationship at two pressures and Fig. 6, at four moisture contents. Fig. 5 can be used to estimate the probable improvement ratio that can be attained on any high-moisture coal.

Consumption of Steam

The amount of steam required to remove a unit quantity of water from coal decreases as the total amount of water removed increases. Table 2 shows the measurements made on four lignites dried in the pilot plant at various pressures.

TABLE 2 NET STEAM IN POUNDS USED PER POUND OF WATER REMOVED FROM LIGNITE

Average	1.176	1.266	0.900	0.923	0.702	0.774	0.773

These observations agree with the results of Klinger (4), who measured the steam consumed in an autoclave holding about 4 tons of lignite. The practice in commercial plants has been to dry large lumps of coal. To do so requires a long heating period; up to 100 min. This period has been divided into a preheating time and a steaming time, which have been described.[7] Klinger showed that about 75 per cent of the total steam required is consumed during preheating. The experiments on the pilot plant were substantially in agreement with Klinger's measurements but also showed that, when some lignites are dried, more than 75 per cent of the steam is used during the preheating period if higher final pressures are employed.

In general, it can be stated that the rate of consumption of steam is proportional to the rate of heating the lumps. When the lumps are large, the time of heating will be longer and the rate of heating lower, therefore the rate of consumption of steam will be less than when the lumps are small. Table 2 shows that an average of 0.77 lb of steam is required to remove 1 lb of water from coal. In drying North Dakota lignite at a pressure of 400 psi, 600 lb of moisture are removed from 1 ton, Fig. 4. The removal of 600 lb of water will require $600 \times 0.77 = 462$ lb of steam, and if it is assumed that 75 per cent of the steam is used during a 20-min heating period, then the rate of consumption of steam is 1000 lb per hr per ton of lignite being dried at 400 psi pressure. An autoclave having a capacity of 10 tons would require steam at a maximum-demand rate of 10,000 lb per hr for a 20-min heating period. Part of the steam would be supplied from the other autoclave, but the net steam from the boiler would still be required at this maximum rate. The fuel required to dry lignite by this process is estimated to be 4.5 per cent of the plant output, and for subbituminous coal, it is estimated to be 2.3 per cent, assuming in both cases the efficiency of steam generation is 75 per cent.

Effects of Size of Coal on Processing Time

From theoretical considerations of the time required to heat coal of different sizes to a given average temperature, it is evident that the size of the coal will determine the length of the drying period. Through theoretical deductions, Dr. Formanek (5) showed the importance of size in relation to the time required for drying. It was proved by Burke, Schumann, and Parry (6) that the law of squares can be applied to this problem even though the thermal constants may vary with the temperature and temperature with the time. The law of squares states that the time required to heat a body to a stated condition or distribution of heat is proportional to the square of some linear dimension of the body. For irregular lumps of coal, the time required is proportional to the square of the average diameter of the lump.[8] A formula for estimating the time of heating in minutes is as follows:

Estimated theoretical time of heating in minutes $= 7 \times$ diameter (inches) squared

Diameter of lump, in.	Heating time, min
0.25	0.44
0.50	1.75
0.75	3.9
1.00	7.0
1.25	10.9
1.50	15.7
1.75	21.4
2.00	27.9
2.50	43.5
3.00	63.0
3.50	85.0
4.00	112.0
5.00	175.0
6.00	252.0
7.00	340.0

[8] If it is assumed that average lignite has a specific heat of 0.58, a density of 78 lb per cu ft, and a thermal conductivity of 0.25 Btu per deg F per sq ft per hr per ft, the time required to heat the lump to any average temperature can be estimated from known laws of heat conduction using the graphic solution referred to in reference (6). If it is assumed that the temperature rise of the center of the lump is 95 per cent of the surface temperature rise, the time of heating in minutes equals 7 times the average diameter in inches squared.

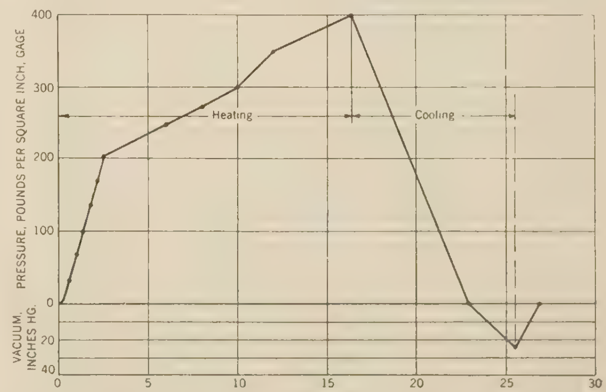

Fig. 7 Heating and Cooling Periods When Drying Subbituminous Coal at 400 Psi Pressure
(Size of coal $^1/_4$ in. $\times$ $1^1/_2$ in.)

These estimates of the time of heating are in fair agreement with experimental measurements. European practice in large commercial plants has shown that cycles lasting 140 to 180 min are necessary to dry large lumps averaging 4 to 6 in. diam. One experiment conducted at the University of North Dakota on lumps of coal sized up to $1^1/_2$ in. diam is illustrated in Fig. 7. In this experiment, the time of heating was about 15 min and the time of cooling about 10 min.

From these considerations, it can be concluded that small stoker coal of a size less than 1 in. may be dried with steam in periods as short as 10 to 15 min.

Changes in Physical and Chemical Properties

Although alterations occur in the ultimate constituents during steam drying, the changes are so slight that they have but little significance. Dr. H. Klein (7) and Lavine (3) showed that approximately 30 cu ft of CO_2 is released when 1 ton of lignite is dried at 175 psi pressure. Some nitrogen is released, and the liberation of these inert gases improves the calorific value of the coal substance, but the effect is slight. A small amount of ash is leached out by the drying process.

Fig. 8 (*A*) Subbituminous Coal Before Drying. (*B*) Subbituminous Coal After Drying With Steam at 200 Psi Pressure

All of the coals tested disintegrated to some extent. The data on screen sizes, in Table 1, indicate the average disintegration. Experiments on fresh 2 × 4-in. lignite show that about 15 per cent of the processed residue will pass a 1-in. screen after drying. Other experiments on lumps up to $2^1/_2$ inches in size indicate that the disintegration is less on the small sizes and amounts to about a 10 per cent reduction in average size. Fig. 8, showing large lumps of subbituminous coal before and after drying, indicates the amount of disintegration and the way in which the lumps fracture. This sample was handled carefully to avoid mechanical breakage.

TABLE 3 ESTIMATED COST OF CONSTRUCTION OF FLEISSNER STEAM-DRYING PLANTS

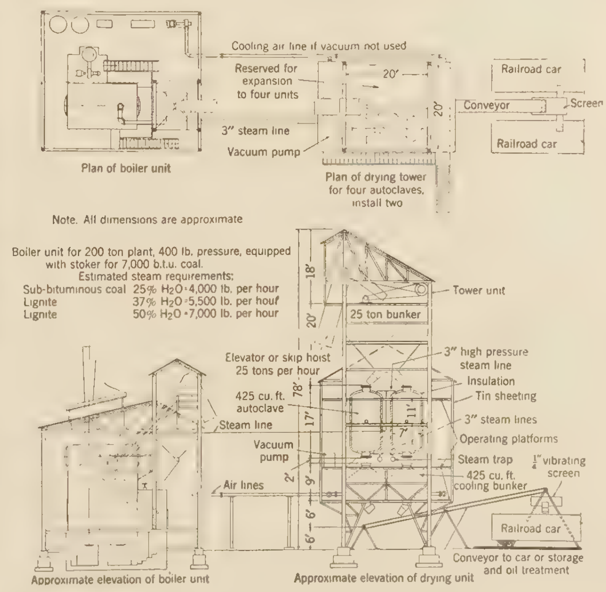

Fig. 9 Schematic Layout for Fleissner Drying Plant
(Capacity, 200 to 400 tons wet lignite per day.)

Commercial Application of Fleissner Process to American Coals

A schematic design was made of a 400-ton plant to estimate costs, Fig. 9. Several equipment manufacturers in the United States contributed estimates of the cost of different parts. These costs are summarized in Table 3, which shows that a plant having two 425-cu-ft autoclaves will cost approximately $80,000 and a plant with four autoclaves will cost about $105,000 either in North Dakota or in Wyoming. The capacity of these plants

[a] Cost in dollars.

will depend upon the length of the drying cycle. If 140 min are required for drying, the capacity will be 200 and 400 tons a day, respectively, and if the drying time can be reduced to 35 min, the capacity will be approximately 800 to 1600 tons daily. At 1600 tons daily, the steaming rate would be approximately 22,000 lb per hr for each pair of autoclaves, assuming a 13-min steaming period, and the maximum steam rate for a plant having four autoclaves would be 44,000 lb per hr.

Total investment and operating costs are estimated in Table 4, for plants operating 200 and 300 days a year on cycles of 70 and 140 min. As shown, the total cost of drying per ton of raw coal ranges from 98.8 to 35 cents, and the cost of drying is reduced one third when the drying time is halved, indicating that the cost of drying may be reduced to about 25 cents a ton if a drying time of 35 min can be attained.

[a] Excludes dealer's margin.
[b] Available heat is net heat minus the sensible heat of products of combustion above 32 F, when stack gases leave the furnace at 500 F with 30 per cent excess air.
(*A*) Millers Creek bituminous slack coal; $5.20 a net ton at Duluth, Minn., available heat = 22,900,000 Btu per ton.
(*B*) Raw lignite; $1 per ton at mine; available heat = 10,600,000 Btu per ton.
(*C*) Dried lignite, 140-min cycle, 400 psi steam pressure, 400-ton plant operating 200 days a year; available heat = 16,500,000 Btu per ton; cost at mine = $2.46 per ton.
(*D*) Dried lignite, 70-min cycle, 400 psi steam pressure, 800-ton plant operating 200 days a year; available heat = 16,500,000 Btu per ton; cost at plant = $2.15 per ton.
(*E*) Dried lignite, 70-min cycle, 400 psi steam pressure, 800-ton plant operating 300 days a year; available heat = 16,500,000 Btu per ton; cost at plant = $2 per ton.
(*F*) Raw subbituminous coal; available heat = 15,172,000 Btu per ton; cost at plant = $1.40 per ton.
(*G*) Dried subbituminous coal, 140-min cycle, 400 psi steam pressure, 400-ton plant operating 200 days a year; available heat = 19,846,000 Btu per ton; cost = $2.41 per ton.
(*H*) Dried subbituminous coal, 70-min cycle, 400 psi pressure, 800-ton plant, operating 200 days a year; available heat = 19,846,000 Btu per ton; cost = $2.17 per ton.
(*I*) Dried subbituminous coal, 70-min cycle, 400 psi pressure, 800-ton plant operating 300 days a year; available heat = 19,846,000 Btu per ton; cost = $2.04 per ton.

Table 5 and Fig. 10, show the estimated costs of available heat from bituminous coal and raw and dried lignite; Table 5, also includes costs for raw and dried subbituminous coal at various destinations. Available heat, instead of gross heat, is used in this comparison as it allows for the combustion characteristics of the different fuels. "Available heat" is defined as the amount of heat in excess of stack losses when fuel is burned at either 14 per cent CO_2, or with 30 per cent excess air, and the products of combustion leave the furnace at 500 F. The high moisture content of raw subbituminous coal and lignite and the relatively large amount of inert gases produced when these low-rank fuels

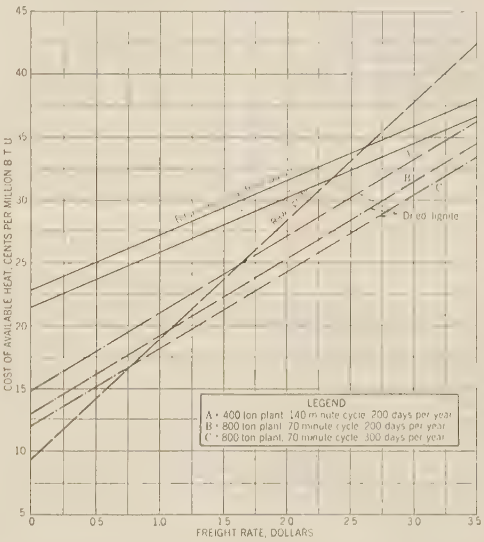

FIG. 10 DELIVERED COSTS OF BITUMINOUS COAL AND RAW AND DRIED LIGNITE

are burned cause disproportionate stack losses, compared with stack losses when the higher-rank fuels are burned. These losses do not permit good comparisons on the basis of gross heating value.

Table 5 presents the cost of available heat exclusive of the dealer's margin of profit or expense. The costs in column *A* are for available heat from bituminous coal delivered from the docks at Duluth. The costs shown in the other columns are for available heat from raw and dried subbituminous coal and lignite delivered from the mines. From this table the probable extension of markets for dried lignite can be determined. For example, the freight rate on bituminous coal from Duluth to Minneapolis is $1.32, making the cost of available heat 28.6 cents per million Btu. The freight rate on lignite to Minneapolis is $2.51, and the cost of available heat is 33.1 cents per million Btu. Raw lignite, therefore, cannot compete with bituminous coal in Minneapolis. On the other hand, the estimated cost of heat from dried lignite in Minneapolis is 27.4 cents per million Btu. Similarly, the freight rate on bituminous coal from Duluth

to Brainerd, Minn.,[9] is $1.27, which makes the cost of available heat 28.1 cents per million Btu. The freight rate on lignite is $2.47, and, if lignite can be dried under the conditions described in column E, the delivered cost in Brainerd, Minn., will be 27 cents per million Btu which is less than the cost of heat from bituminous coal. These comparisons indicate that the eastern markets for lignite could be extended approximately 150 miles by steam drying.

A Method of Determining the Pressure Drop for Oil-Vapor Mixtures Flowing Through Furnace Coils

By F. W. DITTUS[1] and A. HILDEBRAND[1]

This paper outlines a procedure for calculating pressure drops which has been used by the authors in the design of furnaces over a period of several years. The resultant total pressure drops have in each case checked closely with the calculated values. The equations given in the paper are set up to determine the pressure gradient for the part of the furnace where a liquid-vapor composition exists, particularly in the case of a vaporizing petroleum oil. The method as outlined consists of a combination of mathematical equations and graphical solutions.

In THE derivation of the equations in this paper, the following nomenclature is used:

Nomenclature

a = constant in equation for curve of heat content at initial boiling point, Fig. 3, Btu per lb

c_h = slope of heat-content curve for liquid-vapor mixture, Fig. 3 (pseudo specific heat of vaporizing mixtures), Btu per deg F per lb

c_p = slope of curve for heat content of oil at initial boiling point, Fig. 3, average specific heat of liquid, Btu per deg F per lb

D = inside diameter of tubes, in.

f = friction factor for two-phase mixture flowing through tube

F_v = weight fraction of liquid which has been vaporized at any point within heating coil

g = acceleration of gravity = 32.2 fps per sec

h = height of vertical section of heating coil, ft

H = heat content of fluid at any point within heating coil, Btu per lb

H_c = heat content of cold fluid at inlet to heating coil, Btu per lb

H_i = heat content of fluid at its initial boiling point at any given pressure P_1, P_2, P_3, etc., Btu per lb

H_B = heat content of fluid at inlet to or bottom of that section of heating coil lying in a vertical plane, Btu per lb

H_T = heat content of fluid at outlet or top of that section of heating coil lying in a vertical plane, Btu per lb

k_f = slope of flash-distillation curve, Fig. 2, F

k = slope of molecular-weight curve, Fig. 5

L = length of fluid travel, ft

l_t = length of single tube, ft

M = average molecular weight of oil vapor

M_i = hypothetical molecular weight of oil vapor at initial boiling point

n_p = number of tubes operating in parallel

n_v = number of velocity heads lost in each return header

P = pressure at any point within heating coil, psi abs

R = perfect-gas constant = 10.71, volume in cu ft and P psi

T = absolute temperature of fluid at any point in heating coil, deg Rankine

T_i = initial boiling point of liquid at any given pressure P, deg Rankine

u = mean velocity, fps

U = heat-absorption rate of inside tube area, Btu per sq ft per hr

v = mean specific volume of two-phase mixture, cu ft per lb

v_L = mean specific volume of liquid, cu ft per lb

v_v = volume of vapor per pound of two-phase mixture, Fig. 6, cu ft per lb

W = total mass flow rate, lb per hr

$X = \dfrac{ZR}{MP}(2k_fF_v + T_i)$, Fig. 6

y = elevation above any given reference plane, ft

Z = gas-law correction factor (molal volume of vaporized oil divided by volume of equivalent perfect gas)

The units indicated apply to the final equations which will be derived. The derivation of these equations is in absolute units however, for the purpose of eliminating a number of constants.

General Statement of Problem

The engineer is sometimes confronted with the problem of calculating the pressure drop for the flow of a boiling liquid through furnace tubes. As long as the pressures and temperatures within the tubes are such that vaporization is suppressed, the pressure-drop calculation is simple. As soon as the temperature has become high enough to cause vaporization, the pressure-drop calculations become involved, for the reason that the liquid-vapor composition changes all along the tube, resulting in a continual change of the pressure gradient. The equations given in this paper are set up to determine the pressure gradient for the part of the furnace where the latter condition exists; particularly for the case of a vaporizing petroleum oil. The procedure should, within limits, apply also to other fluids, but in such cases a check should be made on the various assumptions to insure that the physical properties of the fluid under consideration do not make the assumptions used in this paper invalid.

As far as the authors know, the general practice in solving a problem of this type is to divide the heating element into a number of convenient sections and calculate by trial-and-error method the pressure drop of each section, starting with the terminal section and moving backward along the heating element, section by section. Since the pressure, temperature, and heat content of the fluid vary all along the tube, this is a rather difficult and time-consuming job. To establish mathematical equations for an exact solution of this type of flow problem for such cases as oil-distillation furnaces is, while perhaps not impossible, certainly impractical because of the number of variables involved in such a problem. A method is herewith presented for solving such problems by using a combination of mathematical equations and

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

graphical solutions. After once becoming acquainted with this method, a relatively rapid and accurate solution of such problems may be obtained.

Principle Used in Calculations

In principle the solution of the problem consists of first calculating the rate of pressure drop per unit length of tube, i.e., $(dP)/(dL)$, at several points in the furnace for each of a number of arbitrarily assumed constant pressures (P_1, P_2, P_3, etc.), then plotting these values as ordinates against the tube length, as shown in Fig. 1. The pressure gradient at constant pressure indicates the rate of pressure drop which would occur at any given point along the tube if the pressure at that point were equal to the assumed constant pressure.

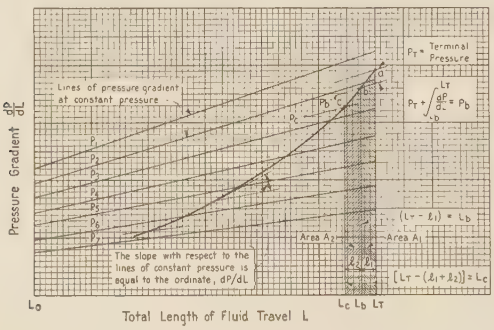

Fig. 1 Method of Graphical Integration to Determine Pressure Gradient Through Oil Furnace

To obtain the total pressure drop involves graphical integration, as shown in Fig. 1. This is accomplished by plotting a curve, beginning at the terminal pressure P_T, of such shape that the area A_1 under this curve between the limits of L_T and $(L_T—l_1)$ (which area represents the pressure drop for the length l_1) when added to the terminal pressure P_T is equal to the pressure P_b established by the intersection b of this curve with the pressure curve P_b at the point $(L_T — l_1)$. This pressure P_b is the pressure within the tube at point L_b. In order to secure the area A_1 under the curve ab the shape for the curve ab must be known. Actually, of course, the point b is unknown, and it is therefore necessary to make an assumption as to location of this point, i.e., the pressure P_b at point $(L_T — l_1)$, and then check if the area under the thus assumed curve ab when added to pressure P_T is equal to pressure P_b. This procedure is then repeated using pressure P_b as a starting point, and using the point P_c then found as a starting point for the next increment of tube length, and so on.

While this procedure is fundamentally a trial-and-error method, it will be found from experience that the solution is simple. The most time-consuming part of the work is to plot the curves of pressure gradient at constant pressures (P_1, P_2, P_3, etc.) against tube length, as shown in Fig. 1. The following discussion is concerned primarily with the simplified method developed for calculating the points necessary to plot these pressure-gradient curves. Experience has demonstrated that the simplifications employed affect the accuracy of the answer but little. Also it has been found that it simplifies matters some to use the heat absorbed instead of the tube length as the abscissa in Fig. 1, as will be explained.

Determining Pressure-Gradient Curve

Before proceeding to set up the various equations, it might be well to review briefly what factors must be considered in determining the pressure-gradient curve for any constant pressure P at any one point within the heating coil.

As a unit mass of liquid passes from the entrance of the heating coil L_0 to the exit or terminal of the heating coil L_T, the liquid absorbs heat equal to the heat absorption of the surface over which the liquid passes. The first simplification that is made is the assumption that the heat-absorption rate per unit area of tube surface is constant, and that therefore the heat absorbed by the liquid is directly proportional to the tube length traversed by the liquid. Thus, the heat content of the fluid can be established at any point along the tube. With this known, and considering the fluid under a constant pressure P, it is possible to calculate the fraction of fluid in vapor form. This permits evaluation of the mean density which in turn allows calculation of the friction loss per unit length of tube, the change in velocity head, and the change in static head, at the point corresponding to this density. In the event the heat-absorption rate is not uniform, the solution can still be secured by breaking up the heat-absorbing surface into a convenient number of sections, for each of which the heat-absorption rate is nearly constant, and then preparing a separate set of calculations for each one of the sections.

Since the rate of heat input per unit area and the tube diameter are assumed to be constant, the heat transferred is directly proportional to length. It is therefore possible to calculate the pressure gradient as a function of the heat absorbed instead of the tube length and thus plot a set of curves showing the pressure gradient as a function of the heat content of the fluid, instead of as a function of lengths, as was shown in Fig. 1. The pressure drop is then obtained by graphical integration in the same manner as is shown in Fig. 1. With this procedure in mind, the necessary equations required for plotting the pressure gradients at constant pressures will now be derived.

Fanning's and Bernoulli's equations state that the total change in pressure when a fluid is flowing through a conduit can be expressed as

$$dP = \frac{fu^2}{2vgD}\,dL + \frac{udu}{vg} + \frac{dy}{v} \quad [1]$$

The first term in the right-hand side of Equation [1] represents the friction loss which is the major portion of the total pressure drop in a furnace. The second term represents the change in velocity head. The velocity head is usually a large factor only in a furnace whose outlet pressure is well below atmospheric. The third term represents the change in gravitational potential or liquid head. In the case of liquids partially vaporized this term is generally very small.

The first step in changing Equation [1] into the desired form for integration is to express the linear velocity u in terms of mass rate and specific volume

$$u = \frac{4Wv}{\pi D^2 n_p} \quad [2]$$

$$du = \frac{4W}{\pi D^2 n_p}\,dv \quad [3]$$

Substituting these in Equation [1], it becomes

$$dP = \frac{8fW^2v}{\pi^2 g n_p{}^2 D^5}\,dL + \frac{16W^2}{\pi^2 g n_p{}^2 D^4}\,dv + \frac{dy}{v} \quad [4]$$

If coefficient of friction f is assumed constant, the specific volume v and the differentials dL, dv, and dy are the remaining variables on the right-hand side of the equation within a portion of the furnace having a constant tube size and the same number of parallel passes.

The average specific volume v is equal to the fraction vaporized F_v times the specific volume of the vapor, plus the fraction unvaporized $(1 — F_v)$ times the specific volume v_L of the liquid, or

$$v = F_v Z \frac{RT}{MP} + (1 - F_v)v_L \ldots\ldots\ldots\ldots\ldots [5]$$

It is next necessary to establish the value of F_v at any point within the heating coil in terms of H, the heat content, and P, the pressure.

The first step in solving for F_v is to plot a flash- or equilibrium-distillation curve from laboratory data. Such a curve, as shown in Fig. 2, can be expressed as a straight line for any given pressure or, if a single straight line deviates too much from the curve, successive sections of straight lines can be used. The equation for such a straight line at any given pressure P is

$$F_v k_f = T - T_i \ldots\ldots\ldots\ldots\ldots\ldots\ldots [6]$$

In most cases only a portion of the liquid is vaporized so that the straight line need only express that section of the curve over which vaporization takes place. By inspecting Fig. 2, which represents a typical equilibrium-distillation curve, it can be seen that the straight line ab expresses the flash-distillation curve very well if the total liquid vaporized is less than 50 per cent for this particular case. If 80 per cent were to be vaporized, it would be necessary to establish another line covering the 50 to 80 per cent vaporized section and make a second set of calculations for that part of the furnace.

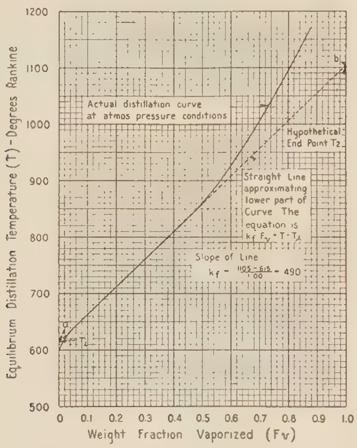

FIG. 2 FLASH- OR EQUILIBRIUM-DISTILLATION CURVE

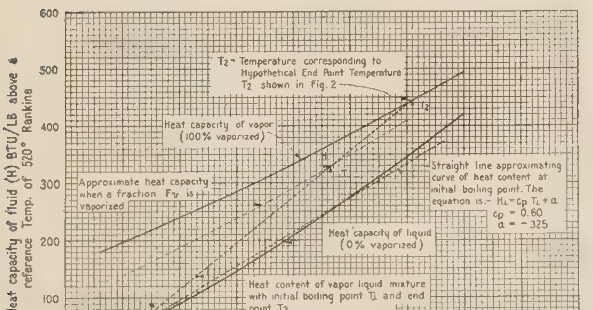

FIG. 3 TYPICAL HEAT-CONTENT CURVE FOR OIL

The next step is to express the value $(T - T_i)$ in terms of the heat content of the mixture of liquid and vapor at any temperature T and any pressure P. This can be done in an approximate manner with the aid of the heat-content curve shown in Fig. 3. In general, no great error is involved if the relation of heat content of the liquid-vapor mixture to temperature at a given pressure is expressed in a linear equation as long as we are concerned only with that section of the flash curve which can be expressed approximately by a linear equation. From Fig. 3, it can be seen that the equation for the heat-content curve of the liquid-vapor mixture at a given pressure P can be expressed by the equation

$$c_h(T - T_i) = (H - H_i) \ldots\ldots\ldots\ldots\ldots [7]$$

The slopes of the curves represented by Equations [6] and [7], i.e., slopes k_f and c_h, are not independent of pressure, but the changes in slopes with pressures are not great and the error in assuming them constant over the entire range of pressures ordinarily occurring within a furnace will be quite small if the slopes used correspond approximately to the furnace-outlet pressure. The reason for selecting the values of k_f and c_h at pressures near the furnace outlet, or near the terminal pressure of a given section if the furnace is divided into sections for reasons previously mentioned, is that near the outlet the fraction vaporized is a maximum, and therefore the pressure gradient is a maximum. Ahead of that point the pressure is higher and the heat content lower, so that a much smaller fraction is vaporized and any errors in pressure gradients are of much less magnitude.

By combining Equations [6] and [7] and eliminating the term $(T - T_i)$, it is possible to express F_v in terms of H

$$F_v = \frac{(H - H_i)}{k_f c_h} \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

The quantity H_i is the heat content of the liquid at the point at which vaporization begins at any pressure P. Therefore, H_i will depend upon the pressure. To express it in terms of pressure, it is convenient first to express it in terms of T_i, which will be done as follows:

In Fig. 3, the lower line is the heat-content curve of the liquid. In general, this curve can be expressed as a simple linear function $H = a + kT$ and the point at which vaporization first begins can be expressed

$$H_i = a + c_p T_i \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

Substituting Equation [9] in Equation [8], the following equation is obtained

$$F_v = \frac{1}{k_f c_h}(H - c_p T_i - a) \ldots\ldots\ldots\ldots [10]$$

The term T_i can be expressed as a function of pressure by the equation proposed by E. R. Cox.[2]

$$T_i = \frac{AB}{A - \log P} \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

where A is a constant and B is the boiling temperature at unit pressure.

The substitution of Equation [11] in Equation [10] results in an equation which is cumbersome to use. For this reason, it is better to assume several pressures and select T_i for each of these pressures from a Cox chart, as illustrated in Fig. 4. The value of T_i thus obtained can then be substituted in Equation [10] to determine the fraction vaporized F_v. In view of this, no further substitution will be made and the expression to be used for F_v in Equation [5] is the one shown as Equation [10]. For simplicity, Equation [10] will not be substituted in Equation [5], but will be carried through these calculations as F_v to be evaluated separately and then substituted in the final solution of the problem.

[2] "Hydrocarbon Vapor Pressures," by E. R. Cox, *Industrial and Engineering Chemistry*, vol. 28, 1936, pp. 613–616.

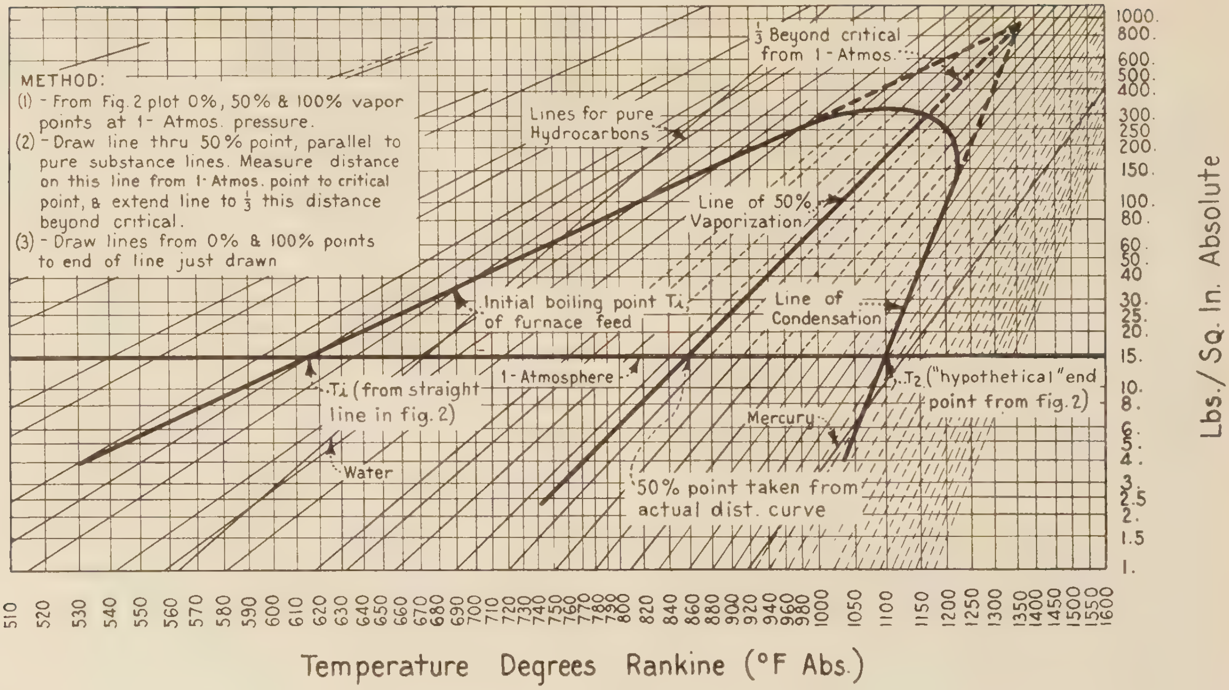

Fig. 4 Cox Chart

The two other variables in Equation [5] for conditions of constant pressure are the values T and M.

The value of M can be fairly well expressed as a linear function of F_v without causing much error. It is relatively simple, however, to evaluate M separately from a curve, such as shown in Fig. 5 (which is based on laboratory data) and then substitute its value directly in the final solution.

The value of T in Equation [5] can be expressed in terms of Equation [6]

$$T = k_fF_v + T_i \qquad [12]$$

Substituting Equation [12] in Equation [5], the latter then becomes

$$v = \frac{ZR}{MP} F_v(k_fF_v + T_i) + (1 - F_v)v_L \qquad [13]$$

Differentiating Equation [13], with P (and hence T_i) constant, gives

$$dv = \left[\frac{ZR}{MP}(2k_fF_v + T_i) - v_L\right] dF_v - \left[\frac{ZR}{M^2P} F_v(k_fF_v + T_i)\ dM\right] \qquad [14]$$

Similarly, differentiating Equation [10] gives

$$dF_v = \frac{dH}{k_fc_h} \qquad [15]$$

Although the molecular weight M can be taken conveniently from an experimental curve, such as that shown in Fig. 5, it is necessary to use a line approximating this curve in order to obtain a simple expression for dM. If the equation of this line is taken as

$$M = k_mF_v + M_i \qquad [16]$$

then

$$dM = k_mdF_v \qquad [17]$$

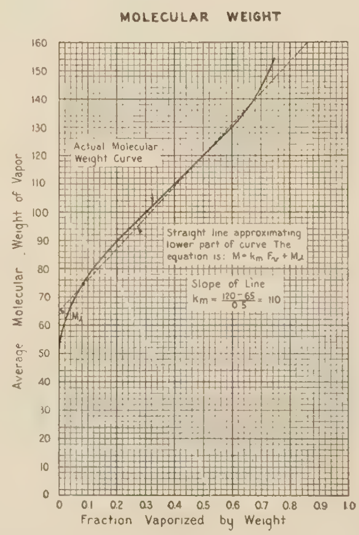

Fig. 5 Molecular Weight

By substituting Equations [15] and [17] in Equation [14], an expression for dv in terms of dH is obtained

$$dv = \left[\frac{ZR}{k_fc_hMP}(2k_fF_v + T_i) - \frac{v_L}{k_fc_h} - \frac{k_mZR}{k_fc_hM^2P} F_v(k_fF_v + T_i)\right] dH \qquad [18]$$

Referring to Equation [4], it is seen that v and dv in that equation can now be expressed as functions of H and P by the use of Equations [10], [13], and [18], but expressions must still be obtained for dL and dy. The expression for dL will be obtained next.

If the absorption rate is constant throughout the furnace, or in

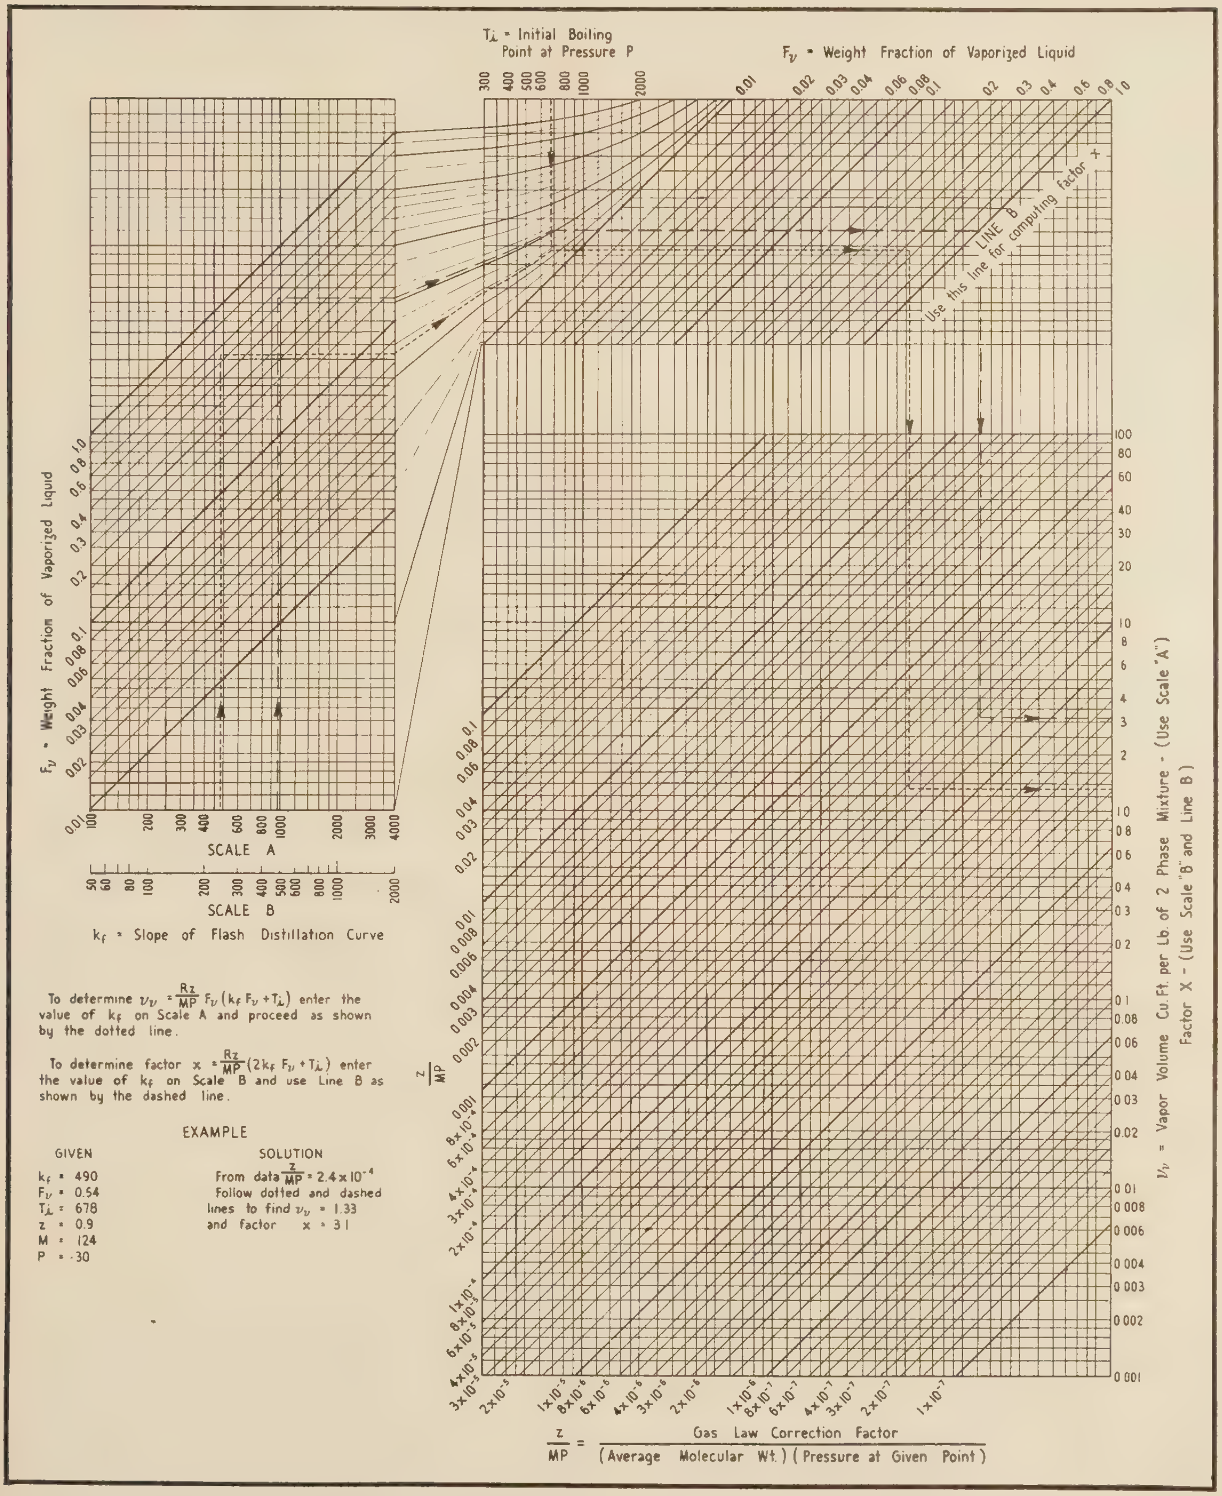

FIG. 6 CHART FOR COMPUTING FACTORS v_v AND x

any given section of the furnace, and if the number of passes and tube size are constant, then the total heat absorbed by the oil up to any point is equal to the heat transferred through the tubes up to that point, or

$$W(H - H_c) = \pi L n_p D U \qquad [19]$$

Differentiating Equation [19] gives

$$dL = \frac{W}{\pi n_p D U}\,dH \qquad [20]$$

The length represented by L is the actual distance traveled by a particle of fluid, but a multiplying factor must be applied to make an allowance for the friction loss in the return header at the end of each tube. If the pressure loss in each header is n_v velocity heads, the equivalent length of tube that will give the same loss of n_v velocity heads is n_vD/f. The friction length per tube will therefore be increased from l_t to $l_t + (n_vD/f)$. The simplest way to take care of this extra friction is to multiply the length dL by the ratio

$$\frac{l_t + \dfrac{n_vD}{f}}{l_t} \text{ or } 1 + \frac{n_vD}{l_tf}$$

When multiplied by this factor, Equation [20] becomes

$$dL' = \left(1 + \frac{n_vD}{l_tf}\right) dL = \left(1 + \frac{n_vD}{l_tf}\right)\frac{W}{\pi n_p D U}\,dH \qquad [21]$$

The method of expressing dy as a function of H may have to be varied somewhat to suit individual cases. Wherever the change in elevation is approximately proportional to the length of fluid travel or the heat absorbed, we can say that the elevation above (or below) the inlet of the coil is

$$y = h\,\frac{H - H_B}{H_T - H_B} \qquad [22]$$

Differentiating Equation [22], we obtain

$$dy = \frac{h}{H_T - H_B}\,dH \qquad [23]$$

Equation [4] can now be rewritten to give dP in terms of H and P by use of Equations [13], [18], [21], and [23]

$$dP = \left[\frac{8fW^2}{\pi^2 g n_p^2 D^5}\left\{\frac{ZR}{MP}F_v(k_fF_v + T_i) + (1 - F_v)v_L\right\}\left(1 + \frac{n_vD}{l_tf}\right)\left(\frac{W}{\pi n_p D U}\right)\right]dH + \left[\frac{16W^2}{\pi^2 g n_p^2 D^4}\left\{\frac{ZR}{k_fc_hMP}(2k_fF_v + T_i) - \frac{v_L}{k_fc_h} - \frac{k_mZR}{k_fc_hM^2P}F_v(k_fF_v + T_i)\right\}\right]dH + \left[\frac{\dfrac{h}{H_T - H_B}}{\dfrac{ZR}{MP}F_v(k_fF_v + T_i) + (1 - F_v)v_L}\right]dH \qquad [24]$$

Rewriting and consolidating

$$\frac{dP}{dH} = \left[\left(f + \frac{n_vD}{l_t}\right)\left(\frac{8}{\pi^3 g U}\right)\left(\frac{W}{n_pD^2}\right)^3\left\{\frac{ZR}{MP}F_v(k_fF_v + T_i) + (1 - F_v)v_L\right\}\right] + \left[\left(\frac{16}{\pi^2 g k_f c_h}\right)\left(\frac{W}{n_pD^2}\right)^2\left\{\frac{ZR}{MP}(2k_fF_v + T_i) - v_L - \frac{k_mZR}{M^2P}F_v(k_fF_v + T_i)\right\}\right] + \frac{h}{(H_T - H_B)\left[\dfrac{ZR}{MP}F_v(k_fF_v + T_i) + (1 - F_v)v_L\right]} \qquad [25]$$

Rewriting Equation [25] to employ the units shown in the nomenclature, and using the term v_v for $\frac{ZR}{MP}F_v(k_fF_v + T_i)$ and X for the term $\frac{ZR}{MP}(2k_fF_v + T_i)$, Equation [25] becomes

$$\frac{dP}{dH} = \left[\left(\frac{12{,}820}{U}\right)\left(f + \frac{n_vD}{12l_t}\right)\left(\frac{W}{1000n_pD^2}\right)^3\left\{v_v + (1 - F_v)v_L\right\}\right] + \left[\left(\frac{0.56}{k_fc_h}\right)\left(\frac{W}{1000n_pD^2}\right)^2\left(X - \frac{k_m}{M}v_v - v_L\right)\right] + \left[\frac{h}{144(H_T - H_B)\{v_v + (1 - F_v)v_L\}}\right] \qquad [26]$$

The values of v_v and X can be readily evaluated by the use of Fig. 6.

In general, it will be found that the friction loss, the first general term of Equation [26], makes up the predominant portion of the total pressure drop. As soon as any fair amount of vaporization takes place, the third term, i.e., the one accounting for the change in static head, can be neglected entirely since the mean density then becomes relatively low. This term is also omitted, of course, when the coil lies in a horizontal plane, since in that case $h = 0$. When the fraction vaporized is very small, such as is sometimes the case in reboilers, the static head may be appreciable, but in that case the change in velocity head is small and the second general term can be omitted altogether.

For all cases of furnace-pressure-drop calculations made by the authors, it was found that no serious error was introduced if both

* H must be chosen sufficiently large so that F_v will not be negative, since F_v cannot be less than zero.

When $F_v = 0$, the pressure gradient, $\frac{dP}{dH} = 2.79\, v_L = 2.79 \times 0.025 = 0.07 \quad \frac{\text{lbs./sq.in.}}{\text{Btu/lb.}}$

the second and the third general term of Equation [26], representing the change in velocity head and static head were omitted in the integration. The total pressure drop in this case is obtained by using the thus simplified equation to calculate the friction pressure drop and then adding the pressure loss due to the increase in the velocity head from the furnace inlet to the outlet and the change in static head based on a mean specific volume. For this particular mode of solution, the equation for the pressure gradient will then become

$$\left(\frac{dP}{dH}\right)_{\text{friction}} = \left(\frac{12{,}820}{U}\right)\left(f + \frac{n_v D}{12 l_t}\right)\left(\frac{W}{1000 n_p D^2}\right)^3 \left(v_v + (1 - F_v) v_L\right) \ldots [27]$$

Column 12 in Table 1, shows the values obtained by the use of Equation [27], while column 18 lists the results of the exact calculations using Equation [26]. It will be noted that the differences are indeed small, although it should be noted also that, once the terms for Equation [27] have been set up, the solution of Equation [26] requires but very little more work.

Simplification of Problem

The solution of the problem can further be simplified for the reason that the values of $(dP)/(dH)$ when plotted against H form a curve that in most cases deviates but very little from a straight line so that it is only necessary to calculate and plot two points for each of the assumed pressures through which straight-line curves can then be drawn. The error caused by this simplification for all the cases the authors have encountered is well within the accuracy that can be expected considering the various simplifying assumptions made in the derivation of the equations.

Since the ease with which the values for the pressure gradients are calculated depends to some extent upon the procedure followed, sample calculations for an actual case will be given. The resultant calculated pressure gradient is compared with the test results in Fig. 7.

Perhaps the one item that is deserving of some comment is the value of the friction factor f for two-phase flow used

in the foregoing equations. The value of this term f can be obtained from the published curves of friction factors plotted against Reynolds number. The Reynolds number is calculated using the average specific volume v of the two-phase mixture, and the viscosity of the liquid. This procedure of establishing the friction factor is substantiated by test results published by Boelter and Kepner.[3]

As in the case of single-phase flow, the friction factor for commercial steel tubes apparently becomes nearly constant with increasingly large Reynolds numbers. The Reynolds number in a furnace is usually quite large so that a constant friction factor is a reasonable assumption to make. In crude-oil furnaces with steel tubes, where the Reynolds numbers are of the order of 1,000,000 to 20,000,000, it has been found by test results that the friction factor is of the order of 0.02, which checks fairly well with published data on friction factors for single-phase flow in commercial pipes.

Typical Pressure-Drop Calculation

The sample calculation to be carried through is for a section of a furnace in which the furnace feed has been split into two parallel streams. There are 34 tubes in each stream (68 total), arranged in a vertical bank with each tube lying horizontally, 10 in. above the preceding tube. The characteristics of the oil are shown in Figs. 2 to 5, inclusive, and the size of tubes, quantity of oil, and other constants describing the furnace and the heat duty are as follows:

a = —325 Btu per lb (see Fig. 3)
c_h = 0.82 Btu per deg F per lb (see Fig. 3)
c_p = 0.60 Btu per deg F per lb (see Fig. 3)
D = 4.5 in.
f = 0.02 (see foregoing discussion)
h = 27.5 ft
H_c = 150 Btu per lb (given condition)
$H_B = H_c$ = 150 Btu per lb (given condition)
H_T = 331 Btu per lb (given condition)
k_j = 490 deg Rankine (see Fig. 2)
k_m = 110 (see Fig. 5)
l_t = 27 ft
n_p = 2 tubes in parallel
n_v = 3 velocity heads per return header
U = 11,700 Btu per hr absorbed per sq ft of inside tube area
v_L = 0.025 cu ft per lb (assumed to be constant)
W = 140,000 lb per hr
Z = 0.9 (assumed to be constant

Substituting these values in Equation [26] gives

$$\frac{dP}{dH} = \left[\left(\frac{12{,}820}{11{,}700}\right)\left(0.02 + \frac{3 \times 4.5}{12 \times 27}\right)\left(\frac{140{,}000}{1000 \times 2(4.5)^2}\right)^2 \left\{v_v + (1 - F_v)\, 0.025\right\}\right] + \left[\left(\frac{0.56}{490 \times 0.82}\right)\left(\frac{140{,}000}{1000 \times 2(4.5)^2}\right)^2 \left\{X - \frac{k_m}{M} v_v - 0.025\right\}\right] + \left[\frac{27.5}{144(331 - 150)\{v_v + (1 - F_v)0.025\}}\right]$$

Consolidating constants, the equation then becomes

$$\frac{dP}{dH} = \left[2.79 \left\{v_v + 0.025(1 - F_v)\right\}\right] + \left[0.0166 \left\{X - \frac{110}{M} v_v - 0.025\right\}\right] + \left[\frac{0.00105}{v_v + 0.025(1 - F_v)}\right]$$

The first step is to assume various values of constant pressure P and, for each of these values of P, assume various values of H, as shown in columns 1 and 2 of Table 1. Actually, in practice it is only necessary to assume two values of H for each given pressure since, as stated, the curves are nearly straight lines, so that two points are sufficient. In Table 1 more than two values of H have been carried through in the calculations for two given pressures to show how much the intermediate calculated points deviate from the straight line. From the Cox chart, Fig. 4, the value of T_i for each of the assumed pressures is then selected, as shown in column 3 of Table 1.

The next step is to solve for F_v, which can be done with the aid of Equation [10] which, with the proper values substituted, will read

$$490 \times 0.82F_v = (H - 0.60T_i + 325)$$

or

$$F_v = \frac{(H - 0.60\,T_i + 325)}{402}$$

The solution for F_v is carried through in columns 4, 5, and 6 of Table 1. From there on, the procedure of calculating the pressure-drop gradients can be clearly followed through from column to column. The resultant total pressure gradients are shown in column 18 and are plotted in Fig. 8. As has been mentioned, and as can be seen from the results listed in Table 1, the velocity-head and static-head terms can be neglected, in which case the work is reduced somewhat, except, of course, it will then be necessary to make an over-all correction for these values.

The pressure gradients, shown in Fig. 8, are then integrated graphically in accordance with the procedure discussed in connection with Fig. 1. The procedure can perhaps be somewhat better understood by following through Table 2, and the actual furnace-pressure curve shown in Fig. 8. The starting point is the given outlet pressure of 32 psi abs. The furnace-inlet pressure arrived at is 144.6 psi abs.

After the pressure gradient has once been established, it is then a simple matter to establish the fraction vaporized and the temperature of the oil at the various points within the furnace by the aid of Equations [10] and [6], respectively. This is done in Table 3 and the results are plotted in Fig. 8.

The foregoing outlined procedure of calculating pressure drops has been used by the authors in the design of several furnaces during the last few years. The resultant actual total pressure drops have in each case checked within a very few per cent of the values calculated by the foregoing procedure. While the authors have not yet had any occasion to apply this procedure to evaporators and other similar equipment, there appears to be no reason why it should not work equally well for such cases.

Discussion

L. M. K. Boelter.[4] This paper represents another step toward the solution of nonisothermal two-phase flow pressure-drop problems. A tentative analytical solution indicates that the pressure drop depends, among others, on the dimensionless modulus

$$\mathbf{R}_g \cdot \frac{\nu_g}{\nu_l} \cdot \frac{W_g}{W_l}$$

where

ν_g = kinematic viscosity of gaseous phase
ν_l = kinematic viscosity of liquid phase
W_g = weight rate of gas
W_l = weight rate of liquid
$\mathbf{R}_g$ = Reynolds modulus of the gas

Thus the procedure outlined by the authors for determination of the friction factor receives partial analytical confirmation.

Vaporization Inside Horizontal Tubes—II Benzene-Oil Mixtures

By W. H. McADAMS,[1] W. K. WOODS,[2] and L. C. HEROMAN, JR.[3]

This paper reports an investigation carried out to determine heat-transfer coefficients and pressure drops for mixtures of benzene and lubricating oil flowing inside a heated horizontal tube, and also includes an analysis of the pressure drops for the runs previously reported (1)[4] for the flow of benzene and of water. The present data cover the following ranges: Velocity, 0.4 to 1.0 fps at the inlet and 16 to 200 fps at the outlet; feed composition, 13 to 94 weight per cent benzene; gage steam pressures, 2 to 120 psi; product compositions, 4 to 76 weight per cent benzene; total pressure drops, 1 to 12 psi. Average over-all coefficients of heat transfer, in Btu per hr per sq ft per deg F, range from 40 to 140 in the preheating section, and 45 to 470 in the boiling section. For a given feed composition the average coefficients per pass in the boiling section increase as vaporization progresses, but pass through a maximum and decrease due to depletion of volatile solvent in the liquid phase. When the same data are grouped by composition of the liquid phase, rather than that of the feed, curves are obtained which are very similar to those obtained for pure liquids.

Nomenclature

THE following nomenclature is used in this paper:

A = area of inside heating surface, sq ft
C_p = specific heat, Btu per lb per deg F
D = diameter, inside, ft
DG/μ = Reynolds number, dimensionless, $= 4w/\pi D\mu$
F = friction, ft-lb per lb
f' = apparent friction factor, Equation [1], dimensionless; f'_m is mean value for one pass; f_i friction factor for single-phase flow based on $4w/\pi D\mu$; at $y = 0$, μ is that of the liquid; at $y = 1$, μ is that of the vapor. For the benzene-oil runs, the length mean μ of the liquid in the preheating section was used to obtain an estimate of f_i
G = mass velocity, lb per hr per sq ft, or lb per sec per sq ft
g_c = conversion factor = 32.2 lb $\times$ ft per (sec^2) (force-pounds)
h = individual coefficient from inside wall to fluid inside tube, Btu per hr per sq ft per deg F
k = thermal conductivity of liquid, Btu per (hr) (sq ft) (deg F per ft)
L = equivalent frictional length, taken as 14 ft per pass for second, third, and fourth passes, and 12 ft for first pass
L_p = perimeter, circumference, ft
P = gage pressure of steam in jackets, psi
p = absolute pressure inside tube, force-pounds per sq ft; p' in cm of mercury, absolute
q = rate of heat flow, Btu per hr
q/A = local flux, Btu per hr per sq ft of inside surface
$(q/A)_m$ = average flux in boiling section, up to any y
R = gas constant $= pv/T$
S = total cross section, sq ft
T = absolute bulk temperature of fluid in tube, deg F absolute; T_m is taken midway through a pass
t_m = temperature, deg C, midway through a pass
U = over-all coefficient of heat transfer, Btu per hr per sq ft (inside) per deg F length-mean difference steam to fluid; substantially equal to h in benzene-oil runs. U and U_m refer to local and mean values in boiling section, respectively, U_p to preheating section
u = average velocity of fluid in tubes, fps
v = specific volume of mixture, cu ft per lb
v_f = specific volume of liquid, cu ft per lb
v_g = specific volume of vapor, cu ft per lb, v_{g1} at entrance to a pass, v_{g2} at entrance to next pass; $v_{ga} = 2RT_m/(p_1 + p_2)$, cu ft per lb of vapor
w = mass rate of flow inside tube, lb per hr
x = weight fraction of benzene in oil; x_1 entering a pass, x_2 entering next pass, x_m midway through a pass, x_0 for feed to first pass
y = cumulative weight fraction of feed in vapor state, dimensionless; y_1 at entrance to a pass, y_2 at entrance to next pass, y_m midway through a pass
Δp = observed decrease in absolute pressure from entrance to one pass to entrance to next, force-pounds per sq ft; $\Delta p'$ in cm mercury
Δt = over-all temperature difference in deg F; Δt_m is length-mean value
μ = viscosity of liquid at bulk temperature, lb per hr per ft; μ', in centipoises; μ'_p, length-mean value in preheating section, centipoises
π = 3.1416
τ = drag, pounds force

Procedure for Testing Benzene-Oil Mixtures

Results of tests on boiling benzene and boiling water in a four-pass, horizontal-tube evaporator have been presented previously (1). It is the purpose of this paper to give the results of tests on boiling mixtures of benzene and lubricating oil. An analysis of the pressure drops for all runs is also included.

The oil used in the investigation was a finished propane-treated bright stock of viscosity S.A.E. 50, and gravity 25.7 deg A.P.I. No light ends could be detected by steam distillation. Liquid viscosities for benzene-oil mixtures were obtained experimentally in a Hepler (falling-ball) viscosimeter at temperatures of 55 C, and less, were extrapolated to 3.7 centistokes by A.S.T.M.-

chart D341-32T, and were finally extrapolated to lower viscosities by interpolating between the known viscosity of benzene at high temperatures and the specification for the oil (164 Saybolt Universal sec at 210 F) Fig. 1.

Only minor modifications had to be made in the apparatus prior to runs on benzene-oil mixtures. It was necessary to pass the hot liquid oil from the vapor-liquid separator through a cooler before the oil could be mixed with the condensed benzene. The frictional resistance of the cooler created a partial vacuum on the intake side of the pump, and caused some air to flow into the oil through leaks in the pipe connections. Accordingly, a large

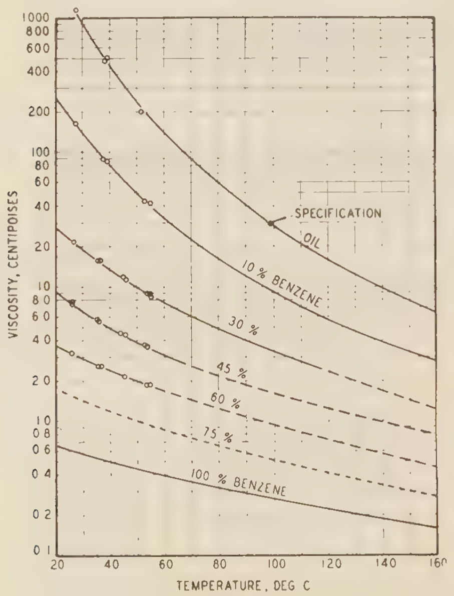

Fig. 1 Viscosity-Temperature Curves for Mixtures of Benzene and Finished Propane—Treated Bright Stock, S.A.E. 50; Gravity 25.7 Deg A.P.I. Curve for Benzene From Bibliography Reference 2

vertical drum was installed between the outlet of the pump and the feed orifice in order to allow this air to separate and be vented through a valve in the top of the drum, before the feed entered the heating section.

Samples of approximately 300 cu cm were withdrawn from the vapor-liquid separator and from the drum in the feed line during each run. One half of each sample was withdrawn at the start of the run, and the remainder at the end of the run; 100 cu cm of each sample was analyzed for volume per cent benzene by simple distillation at atmospheric pressure. The analysis was accurate to 0.5 cu cm of benzene. However, the product sample was taken from the separator at a slightly lower pressure than that at the end of the last steam-jacketed section, so a small amount of benzene may have flashed, causing the reported amount of benzene in the product to be slightly low. In mixing standard samples of benzene and oil, it was found that the volumes were substantially additive. The difference in density between the oil and the benzene is so small that analysis on a volume basis is substantially the same as analysis on a weight basis. The benzene distilled from the heavy oil was water-white.

An over-all heat balance was obtained from the rate of condensation of steam and from the rate of flow and temperature rise of the water in the condenser and in the cooler. The heat balances, corrected for estimated heat losses, checked within 7 per cent at all times, with an arithmetic average of very close to zero. The heat picked up by the cooler varied from 5 to 78 per cent of the total heat transfer. The feed rate reported in the tables was determined from heat and material balances on the test section; the feed rate indicated by the orifice usually checked closely with that from the heat and material balance.

Atmospheric boiling points were determined experimentally for various concentrations of benzene in oil. These data were smoothed by Raoult's law which indicated that the effective molecular weight was a function of the benzene concentration. For pressures above atmospheric the relation between boiling temperature and benzene concentration was calculated from Raoult's law, which involves the vapor pressure of pure benzene, assuming the effective molecular weight of the oil to be independent of temperature. The start of the boiling section for each heat-transfer run could then be estimated, since the initial boiling temperature of the feed was known for the pressure existing at the end of each pass and could be interpolated for the intermediate jackets. A fluid-temperature curve was then interpolated, pass-

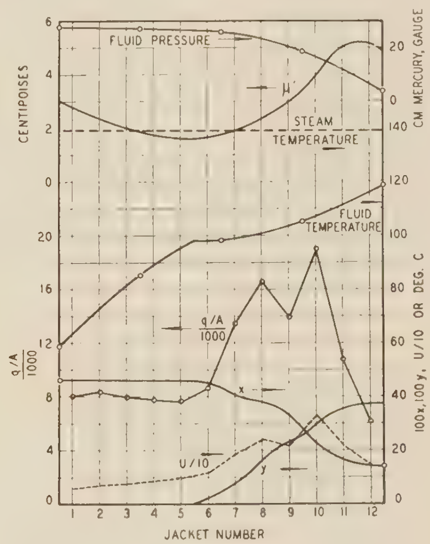

Fig. 2 Data and Calculated Values for Benzene-Oil Run No. BO-22

(1015 lb per hr of feed containing 46 weight per cent benzene; steam gage pressure, 35.5 psi.)

ing through this initial boiling point and thence through the successive observed temperatures of the fluid at the end of each pass. Based on this temperature gradient, the rate of transfer of latent heat in any jacket was obtained by subtracting the rate of transfer of sensible heat from the total heat-transfer rate, based on condensate rates. From the initial feed composition, the feed rate, and the latent heat transferred, both the cumulative weight per cent $100y$ of the feed vaporized, and the weight per cent of benzene $100x$ remaining in the liquid phase at discharge from any specified steam-jacketed section, were calculated. The local over-all coefficients U in Btu per hr per sq ft per deg F were calculated by dividing the heat flux q/A in each jacket by the difference between the saturation temperature of the steam and the average fluid temperature.

Results of Runs on Boiling Benzene-Oil Mixtures

Local Coefficients. The results of a representative run on boiling a mixture of benzene and oil are shown in Fig. 2. In contrast with the runs on benzene or on water, it is noted that a progressive increase in fluid temperature occurs throughout the apparatus. While the decreasing static pressure through the apparatus tends to lower the boiling point of the liquid, the decrease in concentra-

[b] $\Delta p'$ is below 3 cm of mercury, and corresponding values of f'_m are not plotted.
[c] Value of f'_m is based on L of 12 ft, since the first pass did not include a U-bend.

tion of benzene in the liquid more than counterbalances the effect of the pressure drop.

For the run illustrated in Fig. 2, the over-all heat-transfer coefficient in the boiling section starts at 116 in jacket No. 6, passes through a maximum of 330 in jacket No. 10, and then decreases to 147 in jacket No. 12. Not only the heat-transfer coefficients but even the heat flux is larger in the later jackets than in the jacket where boiling begins, despite both the decreasing temperature difference and the increasing viscosity of the liquid. Hence, this initial increase in the heat-transfer coefficient must be ascribed to the turbulence resulting from an increase in the percentage of the feed vaporized.

The operating variables and the over-all results of runs on benzene-oil mixtures are summarized in Table 1. Out of a series of twenty-four runs, four were discarded because of unsatisfactory heat balances, and one because of inaccurate determination of rate of steam condensation in two of the twelve steam jackets. Subsequent to BO-6 all runs were taken at a feed rate close to 1000 lb per hr.

These results, obtained in a given steam-jacketed section are

a function of the distance of that jacket from the entrance to the pass. This function might conceivably be affected by feed rate, feed composition, and steam pressure, as well as being different for different passes. Correlation and presentation of the data are simplified by considering only the over-all results obtained for an entire pass (three jacketed sections).

Average Coefficient for Boiling in Each Pass. The average heat-transfer coefficient U_m for any pass is obtained by dividing the arithmetic average of the heat flux in the three jackets by the length-mean temperature difference in the pass. The results thus calculated are presented in Table 2. The values of $100x_m$ and $100y_m$ are the values existing at the mid-point of the pass, as indicated by graphs, such as Fig. 2. If boiling had not commenced before the end of the first jacket in any pass, the data are not included in Table 2. The heat-transfer coefficients for the preheating section are given in Table 1.

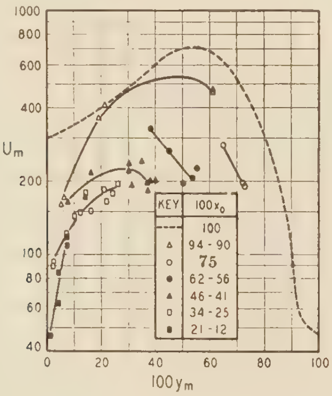

Fig. 3 Average Boiling Coefficients for Each Pass, Versus $100y_m$, for Various Feed Compositions, Omitting Runs at Low Feed Rates

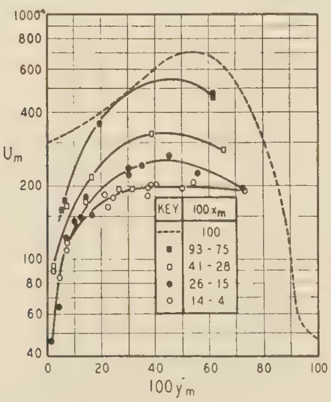

Fig. 4 Average Boiling Coefficients for Each Pass, Versus $100y_m$, for Various Average Compositions of Liquid Phase Midway Through the Pass; Same Data as in Fig. 3

The data of Table 2 are presented in Fig. 3 as a plot of the average heat-transfer coefficient for the pass versus the average cumulative per cent vapor, excluding the data from runs BO-5 and BO-6, which involved considerably lower feed rates. In Fig. 3 symbols are used to designate the various ranges in benzene concentration $100x_0$ of the feed. In general, the coefficient increases with an increase in benzene content of the feed. The plot indicates that the heat-transfer coefficient increases during the initial stages of boiling but subsequently decreases after some critical value of $100y_m$ has been obtained, the critical value of $100y_m$ being a function of the initial feed composition.

Fig. 4 involves the same data as Fig. 3 except that the points are designated, not according to feed composition, but according to average composition $100x_m$ of the liquid phase. The curves of Fig. 4 show a striking similarity to those obtained for pure liquids in this apparatus (1). For a given average composition of liquid, as $100y_m$ increases the coefficient goes through an initial increase. At high values of $100y_m$ (say, greater than 40 per cent) the coefficients may begin to decrease as $100y_m$ increases, due to vapor binding, resulting from insufficient liquid. No data are shown in Figs. 3 and 4 for values of $100y_m$ greater than 73 per cent and, therefore, no extreme cases of vapor binding are involved. There is a tendency for more serious vapor binding to occur when the liquid contains large amounts of benzene.

Fig. 4 is of value primarily because of the light it sheds upon the phenomena; Fig. 3 is the practical plot showing what happens as a given feed is progressively vaporized. For feeds containing 56 to 62 per cent benzene, the coefficient decreases from 320 to 200 as the cumulative vaporization increases from 38 to 54 per

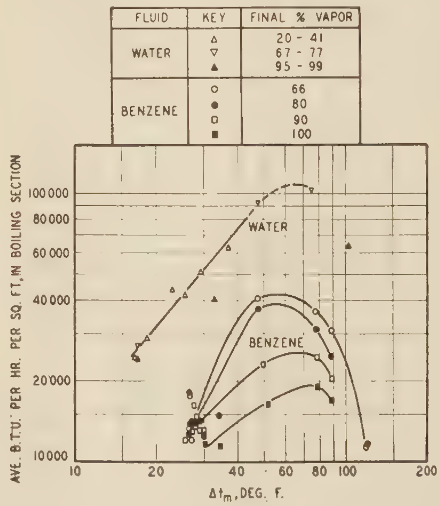

Fig. 5 Average Flux in Boiling Sections Versus Δt_m for All Water Runs and for Benzene Runs Having Feed Rates Ranging From 615 to 618 Lb per Hr, for Various Cumulative Weight Per Cent Vaporized

(For benzene, hot-wall vapor binding occurs at Δt_m exceeding 55–75 F, depending upon extent of vaporization. Data from Bibliography references 1 and 3.)

cent of the feed. Fig. 4 shows that this decrease in the coefficient is not due to vapor binding, but to the depletion of benzene in the liquid phase, the concentration in the liquid phase decreasing from (roughly) 35 to 10 per cent benzene.

The heat-transfer coefficients obtained in runs BO-5 and BO-6, if plotted in Figs. 3 and 4, would be lower than those shown. It is believed that this is due to the relatively low feed rates (545–498 lb per hr) used in these two runs, compared with feed rates averaging 984 for the other runs.

The minor effect of temperature difference probably results from the fact that the heat transferred not only goes into vaporizing some of the benzene but also into heating the residual liquid and vapor. Since coefficients for sensible-heat transfer are less dependent upon temperature difference, it is rational to believe that if large percentages of the heat transferred are used merely to warm the fluid the effect of temperature difference on the heat-transfer coefficient should be minimized. The heat transfer in this instance is rather different in mechanism from the heat trans-

fer by natural convection to liquids boiling at constant temperature outside of horizontal submerged tubes.

For benzene boiling in the same apparatus, with feed rates ranging from 615 to 818, two types of vapor binding were encountered, as shown in Fig. 5, where average flux, $(q/A)_m = U_m \Delta t_m$, is plotted versus the length mean Δt, for various final values of $100y$. Except at low Δt_m where the results were erratic, for a given final weight per cent vapor, the flux goes through a maximum at a critical value of Δt_m. This is due to the formation of a vapor film on the inside wall of the pipe, and is designated "hot-wall" vapor binding.

For a given Δt_m, say 50 F, the average flux decreases with increase in final per cent vapor by weight. This is due to the formation of spray which, at high values of y, is largely carried by the main stream. Such spray as hits the heated wall is evaporated, but since a considerable fraction of the wall is dry, the effective area is reduced, and the apparent coefficient decreases, being based on the entire area, whether wet or dry. This second phenomenon is designated "dry-wall" vapor binding. A few benzene runs were made at higher and lower feed rates and gave results similar to those in Fig. 5.

The data for all the water runs are shown in the upper part of Fig. 5. Although the data are insufficient to warrant curves for

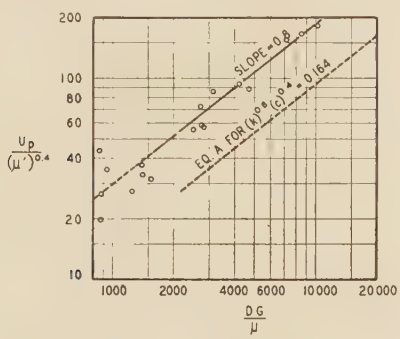

Fig. 6 Preheating Coefficients for All Benzene-Oil Runs, Compared With Equation [A]

various final values of y, it seems likely that dry-wall vapor binding occurred for y of 0.95 to 0.99.

Coefficients in Preheating Section. The warming of fluids inside of pipes, when the temperature of the pipe wall is considerably above the boiling point of the fluid, represents a problem which has not been intensively studied. The problem is especially complicated for the benzene-oil runs, since the Reynolds numbers (860 to 10,000) range from streamline flow, through the critical "dip" region, into turbulent flow. In Fig. 6 the data for the preheating sections are shown for all benzene-oil runs, with $U_p/(\mu')^{0.4}$ plotted versus the Reynolds number based on length-mean viscosity of the main body of the liquid. The dotted line represents (4) the equation

$$\frac{hD}{k} = 0.0225 \left(\frac{DG}{\mu}\right)^{0.8} \left(\frac{C_p\mu}{k}\right)^{0.4} \dots\dots\dots\dots [A]$$

with D taken as 0.0884, k as 0.08, and C_p as 0.48, or any combination of values for k and C_p which make the product of $k^{0.6}$ and $C_p^{0.4}$ equal to 0.164. The solid line through the data gives coefficients twice those from Equation [A]; this may be due to the greater turbulence resulting from the surging flow, and/or to vaporization of benzene in the film next to the hot wall and condensation in the main body of the liquid.

A similar phenomenon was observed in the preheating section of the benzene runs (1).

Pressure Drop

In the present apparatus the pressures at a given point fluctuated somewhat with respect to time, as did the nature of the fluid flow. For example, at the end of the first pass where condensate measurements showed a time-average vapor generation equal to 8 per cent by weight of the feed in a certain run on water, photographs, Figs. 10 and 11 of the previous paper (1), taken a few seconds apart showed stratification into vapor and liquid layers in one case, and in the other an intimate mixture of vapor and liquid. At other times, alternate slugs of vapor and liquid flowed from the first pass. However, as the fluid flowed through two additional passes, and condensate measurements from the first three passes showed 47 per cent vapor by weight, drops of liquid were carried as spray in the vapor stream, which now had a velocity of almost 300 fps. Because of the time fluctuations in the pressures and in the mechanism of the fluid flow the following simplifying assumptions were made:

1 Vapor and liquid flow at the same velocity. The error introduced by this assumption is the greatest at low velocity of the mixture, where stratification into two layers occurs.[5]

2 The volume occupied by the liquid is negligible in relation to that of the vapor. This amounts to discarding the last term in the equation

$$v = yv_g + (1 - y)v_f$$

where v is the volume of 1 lb of vapor-liquid mixture, y is the weight fraction of vapor in the mixture, v_g is the specific volume of the vapor, and v_f is the specific volume of the liquid. The term $(1 - y)v_f$ is not negligible, compared with yv_g at small values of y, but in this range a substantial error is introduced by the assumption of no slip between vapor and liquid.

3 The wall drag τ may be correlated by an equation of the Fanning type, without allowance for any wall traction resulting from vaporization

$$d\tau = (f')\,(L_p dL)\,\frac{u^2}{2g_c v}, \text{ or } dF = \frac{v}{S}\,d\tau = \frac{f'dLu^2}{2g_c\left(\frac{S}{L_p}\right)}$$

which for a round pipe of diameter D reduces to

$$dF = \frac{4f'dLu^2}{2g_c D} \dots\dots\dots\dots\dots\dots [1]$$

wherein f' is the apparent friction factor (dimensionless), L_p is the circumference or perimeter, S is the cross section, u is the average velocity of the mixture at the particular length L, and g_c is a conversion factor (gross dimensions ML/FT^2).

The familiar energy balance, with all terms having dimensions of FL/M, is

$$-vdp = \frac{udu}{\alpha g_c} + dF \dots\dots\dots\dots\dots [2]^*$$

wherein the dimensionless term α allows for nonuniformity in velocity distribution. (As usual for turbulent flow, this term was assumed equal to 1.0.)

By definition

$$u = Gv \dots\dots\dots\dots\dots\dots [3]$$

where G is the mass velocity, equal to w/S, which remains constant. Assumption 2 gives

$$v = yv_g \dots\dots\dots\dots\dots\dots [4]$$

[5] Isothermal runs, wherein no phase change was occurring, would simplify the problem so that estimates of the slip could be made, but in nonisothermal runs the ratio of velocities of vapor and liquid probably changes as vapor generation proceeds.

* In analyzing the pressure gradient for vaporization of a liquid flowing in a heated tube, R. Hoger (*Die Wärme*, vol. 63, 1940, pp. 209–212) employed essentially Equations [1] and [2] but ignored kinetic effects, which are not negligible for conditions encountered in this investigation.

Equations [1, 2, 3, and 4] may be combined, and rearranged, noting that du equals $Gy\,dv_g + Gv_g\,dy$, giving

$$-\frac{dp}{v_g} = \frac{G^2}{g_c}\,dy + y\,\frac{dv_g}{v_g} + \frac{2f'}{D}\,y\,dL \ldots\ldots\ldots [5]$$

Equation [5] was multiplied by $D/2y$, and integrated between sections 1 and 2, calling y, T, and f' constant at y_m, T_m, and f'_m, respectively, giving

$$\frac{g_cD(p_1 - p_2)(p_1 + p_2)}{4G^2RT_my_m} = \frac{g_cD(\Delta p)}{2G^2v_{ga}y_m} = \frac{D}{2}\ln\frac{y_2}{y_1} + \frac{D}{2}\ln\frac{v_{g1}}{v_{g2}} + f'_mL \ldots . [6]$$

Values of f'_m were then calculated from the original data and calculated values, using Equation [6], $D = 0.0884$ ft, $L = 14$ ft (which included the equivalent frictional length of the U-bend). The mean value of y for the pass was read from plot of y versus jacket number, at the mid-point of the three jackets; the values

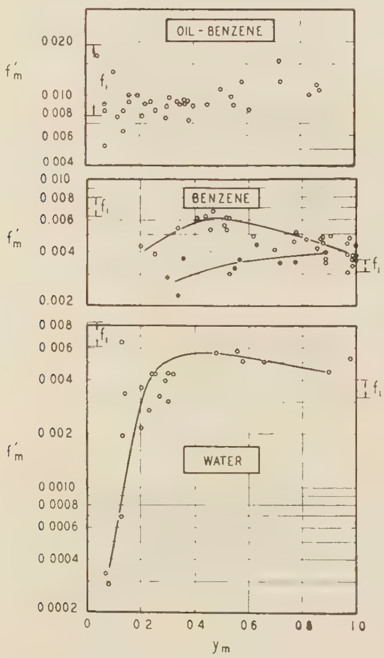

Fig. 7 Apparent Friction Factors Versus $100y_m$
(Black circles designate benzene runs wherein hot-wall vapor binding occurs.)

of v_{ga} were evaluated at the arithmetic-mean pressure as called for by Equation [6], and at T taken midway through the pass. The vapors at these moderate pressures were assumed to follow the gas laws. The values of the friction factor f'_m are shown in Tables 2 and 3. When y is small, there is a substantial percentage of error in estimating y_m which introduces a yet larger error in f'_m, which is obtained by subtracting two kinetic-energy corrections (one for increase in y and the other for increase in volume due to change in T and p) from a term containing the observed pressure drop divided by y_m; unfortunately, when y is small both Δp and y_m are small, hence values of f'_m at low values of y have poor precision. The fluctuation in pressure introduces a substantial percentage of error in Δp, when the latter is small; consequently, for the passes in which $\Delta p'$ did not exceed 3 cm of mercury, values of f'_m were not plotted, although they are given in the tables.

Fig. 7 shows the values of the apparent friction factors, plotted

[a] Based on data of Bibliography (3). Additional data are given in Tables 1 and 2 of Bibliography (1).
[b] $\Delta p'$ is below 3 cm of mercury and corresponding f'_m is not plotted.

versus y_m on semilogarithmic paper. The abnormally low friction factors for water, at values of y of say 0.2 and less, are believed to be due to the error introduced by the assumption that the residual liquid travels at the same speed as the vapor, whereas, at the low values of y, apparently the liquid phase travels at only a fraction of the speed of the vapor. It should be recalled that f'_m was computed by deducting terms representing kinetic-energy changes for both liquid and vapor from the pressure-drop term. Hence, if the deduction for the kinetic energy of the liquid is excessive, the computed value of f'_m will be too low, especially in the range where the weight fraction of liquid is high. The range of ordinates, at y_m of 1, show the usual friction factors (5) f_i for isothermal flow of vapor, and the corresponding range at y_m of 0 shows the usual values of f_i for isothermal flow of liquid. In the range of y_m from 0.4 to 1, the values of f'_m for water are not much higher than would be obtained by a linear interpolation between the terminal values of f_i.

The results for benzene, shown by the open circles of Fig. 7, where the surface was not vapor bound, are similar to those for water. The benzene runs made with a vapor-bound surface (due to excessive wall temperature), shown by the black circles, give lower values of f'_m, probably due to the fact that viscosity of the vapor film is less than that of a liquid film of the same substance.

The values of f'_m for the benzene-oil runs, shown in the top section of Fig. 7, are quite erratic. This results from the fact that the range of Reynolds numbers for all liquid (at $y_m = 0$) is greater than for benzene. Because of the wide variation in benzene content of the feed, f_i ranges from 0.0076 to 0.019. Since the oil could not be vaporized under the conditions used, the f_i range is not shown for y_m of 1.0. The values of f'_m average 0.01, but would doubtless decrease at high Reynolds numbers characteristic of high velocity of flow in pipe stills. A correlation of the values of f'_m might be had in terms of a Reynolds number based on μ at the wall, which would be the viscosity at the wall temperature, of the equilibrium liquid at the existing temperature and pressure. However, it seemed unsafe to extrapolate the viscosities from 55 C to temperatures as high as 176 C.

Heat Transfer Versus Pressure Drop. Fig. 8 shows a plot of pressure drop per pass as abscissas and the mean U per pass as ordinates, and includes preheating data for all runs, and data for the boiling section for those passes where the final y did not exceed 0.74 for all the water runs, those benzene runs where serious hot-wall vapor binding did not occur (i.e., benzene runs where gage steam pressures were below 35 psi), and all the benzene-oil runs. For a given $\Delta p'$, the values of U_m are highest for water, next highest for benzene with moderate Δt_m, and lowest for benzene-oil mixtures, depending upon $100x_m$, the per cent benzene in the liquid midway through the pass. The benzene-oil runs could also be subdivided as to viscosity of the liquid. For a given liquid the curves are flat, and where binding is encountered at high values of $\Delta p'$, the points fall below the curve.

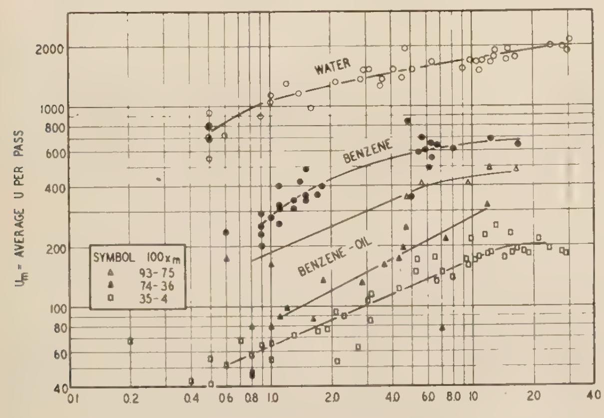

FIG. 8 AVERAGE COEFFICIENTS PER PASS IN PREHEATING AND BOILING SECTIONS, PLOTTED VERSUS PRESSURE DROP PER PASS
(Curves for all water runs, all benzene runs for steam pressures below 35 psi, and all benzene-oil runs; omitting runs wherein the final y exceeds 0.74.)

CONCLUSIONS

1 The coefficients for preheating benzene-oil mixtures are considerably higher than would normally be expected (Fig. 6), and it is concluded that this is due to the surging nature of the flow, and/or to boiling in the film and condensation in the main stream. A similar effect was noted in the benzene runs.

2 Vapor binding, due to spray formation and insufficient wetted area, occurred in the benzene-oil runs (Fig. 4), but to a lesser extent than with benzene, since the oil was substantially nonvolatile and a liquid residue was always present.

3 A further analysis of the benzene runs (Fig. 5) shows both dry-wall and hot-wall vapor binding; the latter type was apparently not encountered in the benzene-oil runs.

4 The pressure-drop data for benzene-oil mixtures, benzene, and water are reported in terms of apparent friction factors (Fig. 7); further data are needed to clarify the situation.

5 In the region where serious vapor binding did not occur, the average heat-transfer coefficients per pass correlate fairly well with pressure drop per pass (Fig. 8), both for the preheating and boiling sections, for the runs on benzene-oil mixtures, benzene, and water.

ACKNOWLEDGMENT

The authors acknowledge the donation of the oil used in the tests from the Humble Oil and Refining Company, Baytown, Texas, as arranged by Dr. Henry D. Wilde.

Discussion

M. A. MAYERS.[6] It seems possible that the concentration of oil droplets along the axis of the tubes, which appeared somewhat unaccountable, might be explained by the phenomenon that causes a clear space adjacent to a hot surface in a dust-filled space or stream. This phenomenon has been described and analyzed by Cawood[7] and Watson;[8] it has been applied to smoke-precipitating apparatus by Watson[8] and Blacktin,[9] and has been used

to prevent the collection of smoke and soot on the windows of smoke meters, using light-absorption methods.[10] There may be a question whether this effect would be observed in flows of as high Reynolds number as in the authors' experiments, but, if it were, the apparent repulsion of particles from a hot surface would account for the observations. It is to be noted that, if the fluid were being cooled, rather than heated, concentration of droplets along the axis from this cause would not be expected.

R. L. Scorah.[11] The authors have not made clear in the paper whether they are dealing with simple over-all heat-transfer coefficients which apply only to the particular type of apparatus employed, or the more fundamental film coefficient. Perhaps the question could be answered best if we could have a short statement regarding: (*a*) the method of determining the heat input of each pipe section, including any corrections found necessary; (*b*) the methods used in determining the temperature of the inside surface of the tube, and the temperature conditions within the flowing fluids; (*c*) the methods employed to study the velocity conditions throughout the length of the tube; and (*d*) a brief statement of the procedures found necessary to estimate the kind of heat-transfer coefficients here reported from a set of observed data.

Authors' Closure

In reply to Mr. Mayers, we share his doubt that the hot-surface effect has a bearing on the phenomena described in the present paper. The remainder of the closure deals with the questions asked by Professor Scorah.

As stated in the second column of page 194, all coefficients were over-all values based on over-all temperature differences. In the benzene-oil runs the resistance on the oil side is so large, relative to those of the tube wall and steam side, that little error would be introduced by assuming that the over-all and oil-side coefficients are substantially equal. The answers to questions (*a*) through (*d*) are as follows:

(*a*) As stated on page 194, the heat input to each section was determined from condensate rates from each section.

(*b*) Tube temperatures were not measured or calculated.

(*c*) Linear velocities were not measured. The mass velocity through the tube is necessarily constant and was calculated from the relation $G = w/S$. As stated on page 194, w was calculated from heat and material balances, and the over-all heat balances checked within 7 per cent; furthermore this value of w was supported by the orifice-meter measurements of feed rates. S was taken as $\pi D^2/4$. The terminal linear velocities were calculated by dividing G by ρ.

(*d*) The procedure used to calculate the over-all coefficients for the benzene-oil runs is given in the second column on page 194. The procedure for runs on water and benzene, together with a detailed description of the apparatus, is given in reference (1).

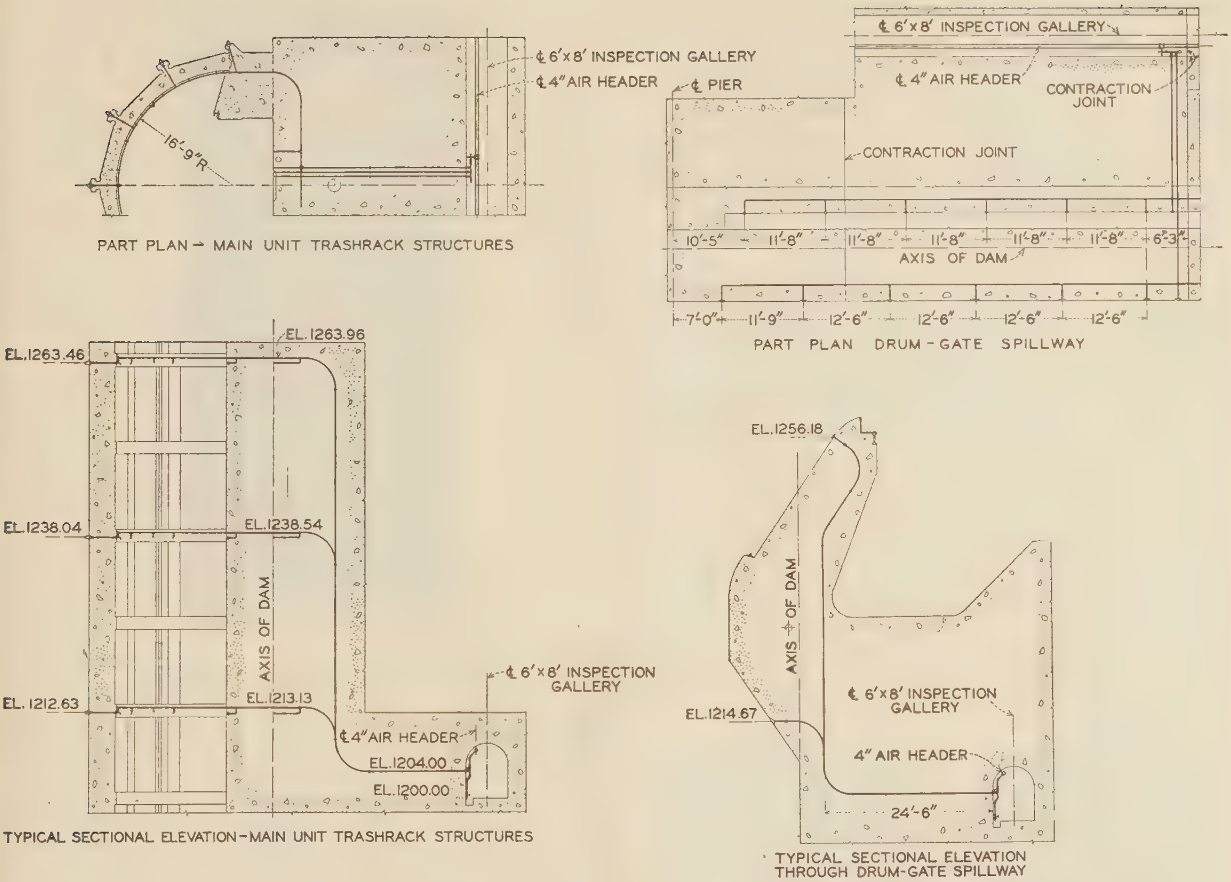

Fig. 1 Typical Orifice Locations in Front of Trash-Rack and Drum-Gate Spillway Structures

Ice Prevention by the Air-Lift System at Grand Coulee

By T. G. OWEN,[1] DENVER, COLO.

This paper deals with the results of a laboratory study of orifices for an air-lift deicing system at Grand Coulee Dam. The investigation included the testing of single- and multiple-hole arrangements of orifices of the short-tube type, the diverging-tube type, and various combinations of both. Flow patterns were studied with these various orifices discharging upward, horizontally, and downward. Special attention was devoted to the freezing phenomenon, and rules for designing a satisfactory nonfreezing orifice were proposed. An orifice was developed which gave a satisfactory balance between flow pattern, economy of operation, and nonfreezing characteristics.

One of the difficulties which has developed in connection with operations at Grand Coulee Dam, of the Columbia Basin Project, Washington, is the formation of ice in front of the trash racks and drum gates. Unless this condition could be adequately corrected during winter weather, it would prove to be both detrimental to good operation and dangerous to the structure. Temperatures of —28 F and of several days' duration have been recorded at the dam site. The problem confronting the designing engineers has been to develop a system whereby the reservoir surface immediately adjacent to the upstream face of the dam could be maintained free of ice. Many methods of accomplishing this result were studied but discarded in favor of the air-lift system because of its simplicity. In the air-lift system compressed air is forced into the reservoir adjacent to the structure at a depth at which the water temperature is at or near that corresponding to maximum density. The stirring and mixing action of the rising air induces the upward flow of

relatively warm currents of water which either melt the ice or prevent its formation.

A typical plan and section of the proposed location of the orifices in front of one trash rack and in front of one drum gate are shown in Fig. 1. Provision is made to introduce air at three different elevations in front of the trash racks and at two separate levels in front of the drum gates. This feature allows air to be introduced at a depth equal to or greater than 10 ft, which has been found to be the minimum depth for best results, regardless of the reservoir elevation.

Laboratory Tests of Orifices

The problems of determining the best size, shape, and direction of discharge of the orifice and the cooling effect due to expansion of the air at the orifice exit were studied in a 1 to 1 scale model in the hydraulic laboratory of the Bureau of Reclamation at Denver. The laboratory investigation was divided into two parts: (1) A preliminary examination of several orifice designs; (2) a detailed study concerning the cooling effect due to expansion.

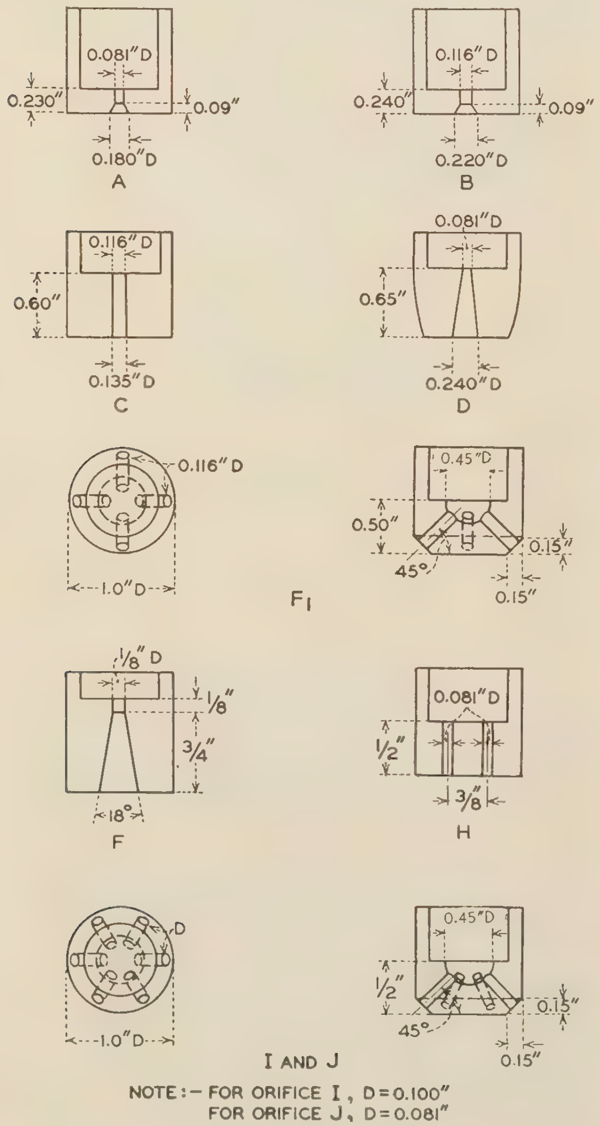

Fig. 2 Orifice Details

Fig. 3 Typical Vertical Discharge Flow Pattern at 3 Psi Differential Pressure; Orifice C

In the preliminary tests, the equipment consisted of a glass-sided tank, near the bottom of which was located the orifice to be tested. The orifice was connected with a high-pressure air line, and a throttling valve was placed in the line to control the pressure. Air-line pressure at the orifice and static water pressure at the orifice elevation were measured by mercury U-tubes, and the difference between these two observed pressures gave the differential pressure across the orifice.

In the experiments on orifices A, B, and C, the tests were purely visual. The general details of these orifices are shown in Fig. 2 and a typical flow pattern, in Fig. 3. From these tests, it was determined that discharge directed vertically downward gave the best flow pattern, the criterion being the largest cross-sectional area of the rising air current and the fineness of division of the air bubbles. It was observed further that an orifice of type C gave a better pattern than type B, which had the same cross-sectional area.

After these initial tests, a gas meter of the displacement type was installed to obtain the discharge characteristics of the various orifices. The flow pattern of orifice D was found to be good but its discharge was too low to establish a strong upward water current. Orifice F produced a good flow pattern and also a good upward circulation of water. The orifices thus far tested had only one hole. The multiple-hole nozzles were then examined. This group embraces orifices F_1, H, I, and J, Fig. 2. The flow pattern from nozzle H was no better than F, and the water current it established was inferior. Nozzles F_1, I, and J all gave excellent flow patterns and induced strong water currents but the discharge capacity of each was excessive. It was thought that if the diameters of the holes in these three nozzles were reduced to lower their discharge capacity, the holes would then be so small that they might easily become fouled or plugged by foreign matter.

Equipment Used for Testing Orifices

For the detailed investigation a special tank was constructed and equipped with instruments. The tank was made 12 ft deep

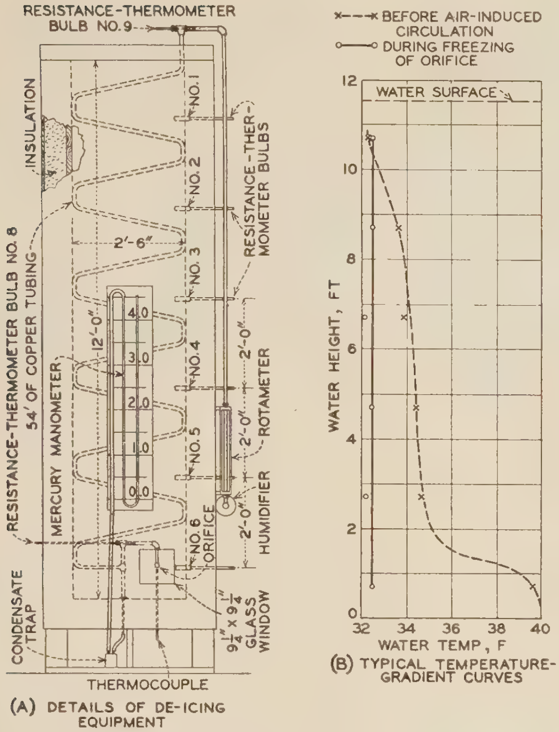

Fig. 4 Details of Deicing Equipment and Typical Temperature-Gradient Curves

so that at least 10 ft of static waterhead could be imposed on the orifice. Inside the tank, about 54 ft of $^3/_4$-in. copper pipe was placed in coils at the end of which was located the orifice to be tested. In one side of the tank and at the elevation of the orifice, a piezometer opening and a resistance-thermometer bulb were located. Located in the same side of the tank at 2-ft intervals, vertically above the thermometer bulb at the orifice level, were five other thermometer bulbs to determine the temperature gradient during testing. These details are shown in Fig. 4 (*A*). The resistance thermometers were connected through a selector switch to a Wheatstone bridge and the resistance balance was indicated by a very sensitive light-beam galvanometer. The temperature of the air before entering the copper coils was measured by resistance thermometer No. 9, and the air temperature before expansion through the orifice, by thermometer bulb No. 8. Attempts were made to measure the temperature of the air stream issuing from the orifice by using a small resistance-thermometer bulb and also by a thermocouple. However, because of the oscillation of the air jet and the vibration of the thermocouple, it was thought that neither the resistance thermometer nor the thermocouple was continuously surrounded by air alone, and hence the indicated temperatures were unreliable.

Insulating material was placed between the inner and outer tank walls which were separated by 2 × 6-in. studding. The bottom of the tank was insulated and the top was equipped with a close-fitting removable cover, also insulated. The air pressure was controlled by a system of three valves, Fig. 5, so arranged that variations in the supply-line pressure would be minimized. The humidity of the air from the supply line was increased by passing the air through the humidifier, consisting of two atomizers which sprayed water on two porous baffles. Mechanically entrained water was removed by a system of three solid baffles, Fig. 5. From the humidifier, the air passed through the air rotameter, a device for measuring rate of flow. The air rotameter, Fig. 5, consists of an accurately machined glass tube tapered to increase in bore from bottom to top. A spinning metal rotor floats in the air stream and its position, read on a scale on the glass tube, indicates the amount of air flowing. Just above the rotameter, a Bourdon-type pressure gage was located. For more accurate air-pressure measurements, a mercury manometer was used. For visual observation and photographic recording, two $9^1/_4 \times 9^1/_4$-in. glass windows were located on opposite sides of the tank at the orifice level.

Testing Procedure

Before starting a test, the tank was charged with about 1200 lb of ice in pieces of about 25 lb each. The initial temperature gradient as indicated by thermometer bulbs Nos. 1 to 6, inclusive, Fig. 4 (*A*) was recorded. Fig. 4 (*B*) shows typical temperature-gradient curves. The static waterhead on the orifice was recorded and then the air flow was started. Water and air temperatures, air pressure, and the quantity of air discharged were observed. The differential pressure across the orifice was progressively increased by increments of about 1 psi until the orifice froze or the pressure limit of the apparatus was attained.

The preliminary tests indicated that orifice *F* had the most desirable properties. A check calibration was made on this orifice in the new model, as shown on the pressure-discharge curve plotted in Fig. 6. Tests on the cooling effect due to expansion of the air indicated that the orifice would freeze solidly, forming a cone of ice in the tapered exit when the air temperature before expansion was 32.38 F and the differential pressure was 5.4 psi.

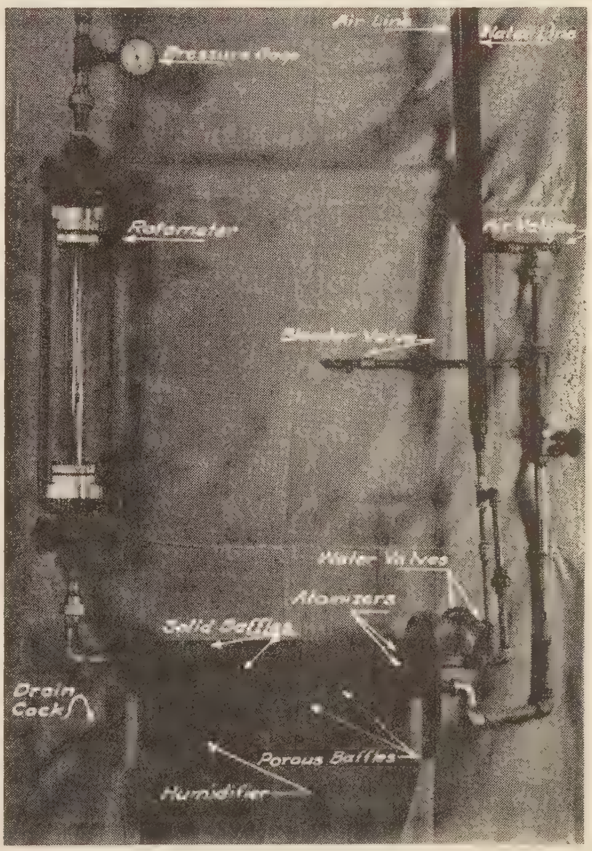

Fig. 5 Humidifying and Air-Metering Apparatus

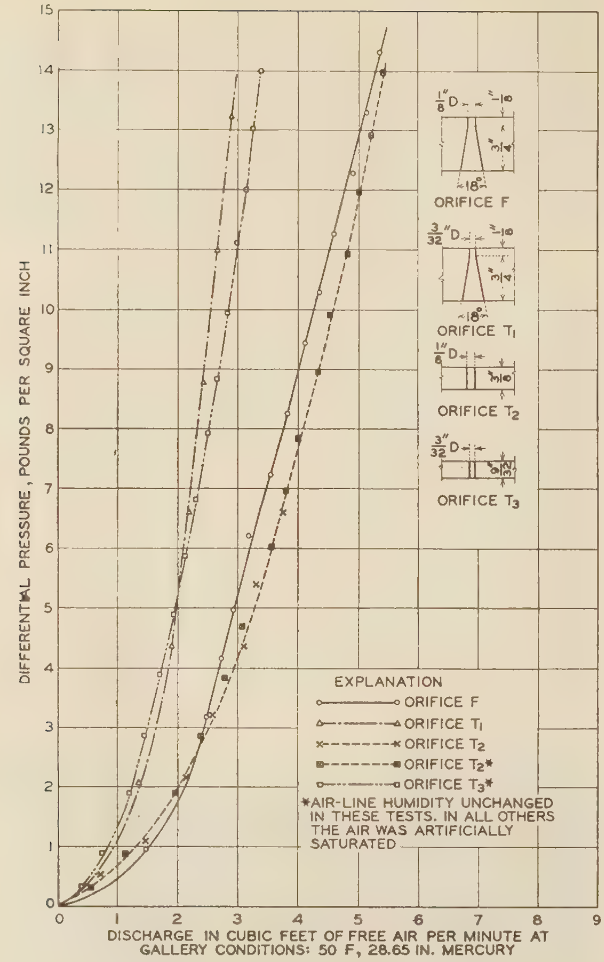

Fig. 6 Pressure-Discharge Curves and Orifice Details

As an alternative design, orifice T_1 was built. It is the same in every detail as orifice F, except that its initial diameter is $^3/_{32}$ in. instead of $^1/_8$ in., which makes its area roughly one half that of orifice F. The calibration curve for this orifice is shown in Fig. 6. Temperature tests were made but the range of air temperature before expansion was too high to cause freezing. The highest differential pressure during the test was 17.54 psi, and the air temperature before expansion was 35.39 F. No further temperature tests were made on this orifice.

Orifice T_2 was tested because it was believed that it would have a lesser tendency to freeze than an orifice having a tapered exit, such as F or T_1. The general dimensions and calibration curve are shown in Fig. 6, and Fig. 8 shows orifice T_2 during a freezing cycle.

Orifice T_3 is a short tube similar to T_2, having its length equal to 3 diameters, Fig. 6. Its area, however, is approximately one half that of T_2. The calibration curve for this orifice is shown in Fig. 6. At this point in the test program, it was decided to adopt orifice T_2 so no further temperature investigations were conducted on T_3.

Ice Formation in the Orifice

From data on the freezing characteristics of orifice T_2 a "critical freezing curve" was constructed by plotting air temperature before expansion against differential pressure Fig. 7(A). This curve passes through the points which lie furthermost to the left and upward. Thus, it divides the temperature-pressure plane into two regions, i.e., one region lying upward and to the left of the curve, in which no combination of initial air temperature and differential pressure will cause freezing; the other lying downward and to the right of the curve, in which all combinations of initial temperature and pressure result in ice formation in the orifice. Ice formation in the orifice is a function of at least the differential pressure across the orifice, the air temperature before expansion, and temperature of the surrounding water; but since the air temperature before expansion is, in turn, a function of the temperature of the surrounding water, the initial air temperature was chosen as one of the co-ordinates for the freezing curve.

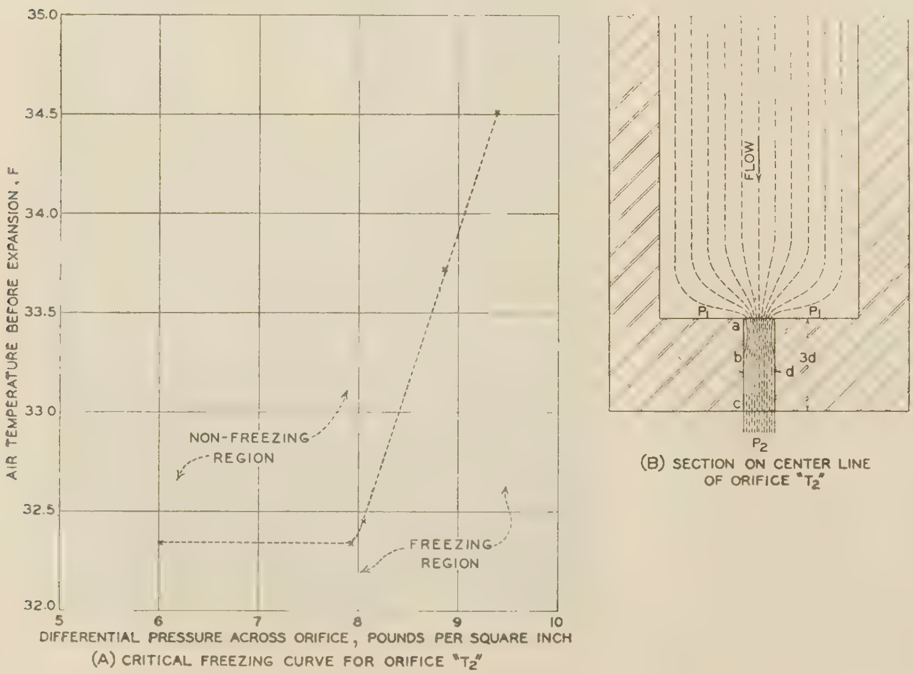

Fig. 7 Critical Freezing Curve and Diagram for Orifice T_2

(*A*) Unobstructed flow prior to ice formation

(*B*) Deflected and restricted flow, due to ice formation

(*C*) Large dense ice cone, completely restricts flow

Fig. 8 Orifice T_2 Discharging at 19.25 Psi Differential Pressure; Air Temperature Before Expansion, 32.37 F
(Thermocouple is seen immediately below orifice.)

In one test, the air temperature before entering the cooling coils was purposely raised about 90 deg F higher than in other tests, but the temperature before expansion was found to be about the same as in other tests. This indicates that the air temperature before expansion will be sensibly the same as that of the surrounding medium, regardless of its initial temperature.

The critical freezing curve, Fig. 7(*A*), does not give all the data in regard to the freezing of orifice T_2. While it gives the combinations of initial air temperature and differential pressure at which freezing starts, it does not indicate the degree or seriousness of freezing. In the range of initial air temperatures up to about 33 F, it was observed that it was possible to have the orifice freeze solidly at points lying on the critical freezing curve.

However, these instances were exceptions rather than the usual result; generally ice would start to form in the orifice, partially fill it, and then be removed by the passing air. In order to obtain quick freezing and ice cones, such as shown in Fig. 8, the differential pressure was increased to 19.25 psi.

In the range of initial air temperature lying above 33 F, freezing of the orifice was not such a serious factor within the differential-pressure range tested. The start of freezing in the range above 33 F became progressively more and more difficult to detect by visual observation of the jet as the differential pressure necessary to produce freezing increased, until in the vicinity of 10 or 11 psi it could only be detected by the instruments. When the mercury manometer, indicating the air-line gage pressure, showed an increase in pressure, and when the rotameter showed concurrently a decrease in discharge, it was definitely established that freezing had started.

In the region of temperature lying above 33 F, it was observed that the duration of the decreased discharge due to ice formation in the orifice became shorter as the values of temperature and differential pressure necessary to cause freezing became greater. Clearing of the orifice was manifested by a sudden increase in discharge and decrease in differential pressure.

Theory Advanced for Ice Formation in Orifice

In attempting to explain the phenomenon of ice formation in the orifices, the following interpretation is offered. A theoretical analysis was made for expansion of saturated air through orifice T_2, taking the actual values of initial and final pressure and initial air temperature found in one test. The expansion was considered adiabatic and account was taken of the variation of the specific heat of the saturated air with temperature, and of the heat of vaporization and heat of fusion given to the mixture by the moisture which condensed and froze. Thus, by approximation, the final temperature of the gas mixture was obtained, and found to be about 2.34 F. This analysis has taken no consideration of heat transfer from the orifice to the gas mixture, although there must have been some. It will be remembered that this set of values of pressure and initial temperature constituted one point on the critical freezing curve, which means that freezing of the orifice just started under these conditions. The theoretical final temperature of 2.34 F is far below the freezing point and it is difficult to conceive that the orifice whose temperature cannot be greater than that of the surrounding water (32.48 F) could raise the air temperature to such a point that freezing just starts under these conditions. Another question arising from a study of the freezing phenomenon is how frozen moisture particles can stick to the walls of the orifice when moving at such a high velocity, approximately 525 fps or 358 mph for orifice T_2 at a differential pressure of 6.01 psi.

A solution which would satisfactorily explain both of these points is proposed and reference will be made to Fig. 7(*B*). The mixture of air and water vapor at pressure P_1 expands through the orifice to pressure P_2 following the approximate streamlines as shown in Fig. 7(*B*). From point *a* to point *b* the jet contracts, passes through the vena contracta, and then expands again following the walls of the orifice between points *b* and *c*. The cold air cools the walls of the orifice between points *b* and *c* to some temperature which is higher than that of the air and lower than that of the water surrounding the orifice. As the saturated air expands, the temperature drops, resulting in moisture being removed from the air by condensation. The resulting fluid is then a mixture of moisture particles and saturated air, the air temperature being below freezing. It is conceivable that the particles of moisture do not freeze instantly because there must be a heat transfer before freezing can occur and, therefore, because of the high velocity through the orifice, it could be possible that unfrozen moisture particles could come in contact with the walls of the orifice between points *b* and *c*. It will be remembered from studies of refrigeration that a moist finger will stick instantly to a metal surface when that surface is at a temperature of 15 F or lower. This is known as the "stick test." If the walls of the orifice were at 15 F, then the moisture particles would stick instantly upon contact, and freezing of the orifice would start. This hypothesis would satisfy both the question of low air temperature and that of the high air velocity.

It is of interest to note that, for the one point on the critical freezing curve for which the theoretical final air temperature was computed and found to be 2.34 F, the average of this final air temperature and that of the surrounding water is exactly 15 F, which is the highest temperature at which the stick test will occur.

By extending this reasoning further it can be explained why freezing is more serious (that is, the orifice may freeze solidly) when it occurs with the temperature of the surrounding water in the region of 32 to 33 F. The orifices tested in the laboratory were made of wrought iron and lead. The thermal conductivity at 64 F is 20.1 for lead, and 34.9 for wrought iron.[2] For ice, the thermal conductivity[2] is given as 1.26. This means that a temperature gradient plotted from the surrounding water, through the metal forming the orifice and to the inside wall, can be of a relatively flat slope but, from the inside wall through the ice to the cold-air stream, the temperature gradient has relatively a very steep slope. Therefore, when freezing of the orifice starts with the temperature of the surrounding water in the region of 32 to 33 F, the temperature of the inside wall of the orifice can conceivably remain below the melting point, the bond between metal and ice remains unbroken, and the freezing process continues on to ultimate restriction of air flow. Whereas, with a higher temperature of the surrounding water, the freezing of the orifice may start but, as the ice deposit increases in thickness, the temperature of the inside wall of the orifice rises until the melting point is reached, the bond between the ice and metal is broken, the flow-restricting ice deposit is removed, and complete freezing of the orifice is prevented.

Conclusions

From this investigation it was concluded that:

(*a*) The direction of discharge vertically downward from the orifice gave a superior flow pattern.

(*b*) An orifice with an 18-deg tapered exit similar to type *F* gave the best flow pattern of all single-hole types tested. The multiple-hole types were at once abandoned because of the high discharge capacity or because of danger of becoming plugged if the diameter of the holes were decreased so that the discharge would be equivalent to the single-hole type.

(*c*) A discharge of 2 cu ft of free air per min at a differential pressure of 2 psi is sufficient to induce a strong upward water current. This value for discharge is also consistent with practical limits of compressor size required for the Grand Coulee air deicing system.

(*d*) An orifice of the short-tube type (T_2) was found to be somewhat superior to the type represented by orifice *F* as far as freezing is concerned; its flow pattern was not materially worse, and its discharge characteristics about the same. Therefore, this orifice was adopted for use in the Grand Coulee deicing system.

(*e*) When freezing in the orifice occurs with the initial air temperature and surrounding water temperature in the range of 32 to 33 F, the orifice may freeze completely, thus stopping the air flow. No complete freezing was observed in the tests when the temperatures of the air and surrounding water were above 33 F and the differential pressure was within the range available with the laboratory apparatus. However, complete freezing may be possible at higher differential pressures.

(*f*) Freezing of the orifice is a function of the initial air temperature, the differential pressure, the type of orifice, the temperature of the surrounding water, the thickness of the orifice walls, and the thermal conductivity of the material of which the orifice is made. It is presupposed that the air used has a sufficiently high initial humidity so that moisture will be condensed during expansion.

Where the danger of freezing is imminent, a sharp-edged orifice should be used. If, however, an orifice of the short-tube type is used because of its superior flow pattern, the freezing hazard may be decreased by making the operating differential pressure small, the walls of the tube as thin as possible and of a material of high thermal conductivity such as copper.

The hydraulic laboratory in which these studies were made is directed by J. E. Warnock, engineer, and is a section of the materials, testing, and control division, supervised by R. F. Blanks and Arthur Ruettgers, senior engineers, in the Denver office of the Bureau of Reclamation. Design studies and investigations are made under the direction of J. L. Savage, chief designing engineer. S. O. Harper is chief engineer for the Bureau and J. C. Page is Commissioner of Reclamation.

Discussion

P. J. Bier.[3] This paper has presented primarily the laboratory experiments made on various air-discharge nozzles and orifices. It may be of added interest to the average engineer engaged in the design and operation of ice-prevention installations to learn something of the construction and operating features of the system developed for Grand Coulee Dam. As far as operating information is concerned, however, the preparation of the paper is somewhat premature, as data on operation will not be available until the ice-prevention system has been thoroughly tested in actual practice.

When the compressed-air system of ice prevention was first considered in connection with the design of the dam, a review was made of existing literature on the subject. While several installations of this nature were in use here and abroad, useful information was very meager. As far as known to the writer, all present installations were added to the dams after construction. Hence, the Grand Coulee ice-prevention system is presumably the first of its kind which has been designed and built into the structure as an integral part of the dam. The reported success of the ice-prevention systems used at Keokuk Dam and at other dams, and their operating economy was mainly responsible for the selection of this type of installation at Grand Coulee.

The lack of information relative to the best size, shape, and position of the orifice in the air nozzle, also the cooling effect and possible freezing which may be encountered when the expanding air leaves the nozzle, became apparent and the laboratory experiments described in the paper were undertaken at the request of the mechanical-design section. Another laboratory experiment was also made, which consisted of discharging compressed air into a vertical glass tube full of water representing the 1-in. distribution pipes which fill up with water between operating cycles. This demonstrated that, for sizes 1 in. diam and smaller, the water is blown out of the tube when the system is put in service, while for larger sizes the air simply blasts a passage through the water in the tube.

As the usual winter fluctuations of the Grand Coulee reservoir are expected to vary between a low level of 1230 and a high level of 1280, it was necessary to provide protection against ice formation for a 50-ft variation in water surface. This will be accomplished with three sets of air-distribution pipes placed at three different levels for the trash racks in front of the penstocks and pump intakes, and with two sets of distribution pipes at two different levels in front of the drum gates, as shown in Fig. 1 of the paper. A better illustration of the entire installation is given in

OPERATING INSTRUCTIONS

The Ice Prevention-Air System is designed to discharge from two to three cubic feet of free air per minute per nozzle from a depth of eight to fifty-one feet below the water surface. To discharge more than three cubic feet of free air per minute per nozzle, operate parts of the system intermittently.

The table shows gage readings calculated to discharge two cubic feet of free air per minute per nozzle for water surface elevations of two foot intervals. The curve shows the cubic feet of free air per minute that will be discharged through the air nozzles for differential pressures across the nozzles from zero to thirteen pounds per square inch.

The air compressors are to be put in service and operated according to instructions furnished by the manufacturer.

Determine which nozzles to use from the water surface elevation. The operating ranges for air nozzles at different elevations and locations are shown on the diagram. When air is first supplied from the control header to the nozzles, valves "H", "J" and the control valve corresponding to the nozzle elevation should be opened wide, so that a maximum flow of air will blow the water out of the riser pipes. The flow of air may then be adjusted by the control valve until the gage reading shows the desired amount of air flowing. When the system is operating the accumulated moisture should be drained from the line through valve "K".

When the system is not in operation, valves "A", "B", "C", "D", "E", "F", "G", "H", and "N" should be closed and valves "J", "K", and "M" should be opened.

High pressure air from the power plant may be obtained for supplementary service and blowing-out lines by opening valve "N". To protect air compressor's, valve "M" should be closed before opening valve "N".

the isometric view, Fig. 9 of this discussion, which also contains the operating instructions for the system.

The compressed air required for the operation of the system is supplied by four single-stage, water-cooled, motor-driven, rotary-type air compressors, each with a capacity of 380 cfm of air at 40 psi gage pressure. Three of the compressors are located in separate chambers off the 1200-ft gallery in the main dam and one in a chamber off the 1210-ft gallery in the pumping-plant dam. The compressed air is collected in a 4-in. main header run through the gallery, from which the distribution pipes and discharge nozzles are supplied.

The air supply to the various distribution pipes, located at the different elevations to suit the reservoir level, is controlled with globe valves, having plug-type disks, and with gate valves, one for each level. These valves are grouped together in a control header for convenience in operating, as shown in Fig. 10 of this discussion, and each control header is equipped with shutoff and drain valves, strainer, and pressure gage. By means of a table giving a set of calculated pressure-gage readings for various reservoir levels and for a discharge of 2 cfm of free air for each nozzle on the distribution pipe to be placed in service, the operator will be in a position to throttle the globe valve to the required pressure to supply the quantity of air needed for the nozzles. For discharges in excess of 2 cfm, the globe valve will be set for the pressure given in the table corresponding to the reservoir elevation, plus the additional pressure given in the pressure-discharge curve in excess of the 2-lb differential pressure for a discharge of 2 cfm.

The entire system can be operated simultaneously, discharging 2 cfm of free air per nozzle for any one of the distribution pipes,

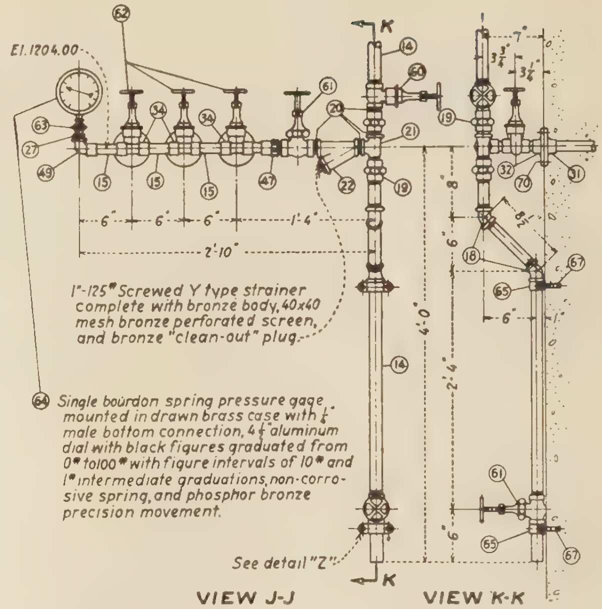

FIG. 10 VALVES GROUPED IN CONTROL HEADER

with three of the available four air compressors operating.

For a discharge of 3 cfm of free air per nozzle for any one of the levels, it will be necessary to operate all four compressors. From the pressure-discharge curve in Fig. 9, it can be seen that discharges up to 5 cfm per nozzle can be provided with differential pressures up to 12 lb. If discharges in excess of 3 cfm per nozzle are desired at any section of the dam, it will be necessary to operate the system intermittently. The table of calculated gage readings given in Table 1 does not cover this remote possibility. The table is based on the assumption that the operating range shown for each distribution pipe or set of nozzles in Fig. 9 is adhered to. This range is 25 ft 6 in. for the two lower sets of trash-rack nozzles and 16 ft 6 in. for the upper set. For the drum-gate nozzles, the range is 42 ft and 24 ft, respectively, for the lower and upper set of nozzles.

The 4-in. main header is made of galvanized steel pipe, the control headers of 1-in. brass pipe, and the distribution lines of 1-in. seamless copper tubing with branches of $^1/_2$-in. copper tubing. The copper lines are connected with cast-bronze solder-joint fittings. The air nozzles are made from bronze with $^1/_8$-in. drilled orifices. Expansion joints are provided for pipe lines running through the contraction joints of the dam. The air-pipe system is cross-connected to a high-pressure air-line extension from the powerhouse, which may be used for supplementary service and for blowing out the operating lines.

While the compressed-air system has been designed for service in front of all trash racks and drum gates, the ends of the drum gates will be protected against freezing to their seats by electrical heating coils embedded behind the face plates of the concrete piers.

The air-lift system was designed by junior engineer J. C. Wright and associate engineer C. O. Selander under the direction of the writer. All mechanical designs are under the general supervision of W. C. Beatty, mechanical engineer, and L. N. McClellan, chief electrical and mechanical engineer, and all designs and investigations are under the general direction of J. L. Savage, chief designing engineer.

The Calculation of Critical Speeds of an Oil-Well Pumping System

By C. R. FREBERG[1] and E. N. KEMLER,[1] WEST LAFAYETTE, IND.

Because of the increasing economic necessity for using light oil-well pumping equipment, steps must be taken to keep loads and stresses at a minimum. Loads can be controlled to some extent by using proper speeds, stroke, and plunger size. Proper counterbalancing has a greater influence on peak loads and stresses than any other item of equipment design. Vibration and critical-speed problems are among the most difficult experienced in pumping systems. Such systems do not lend themselves to mathematical analyses so the authors have undertaken to solve the more complicated problems by replacing such involved systems by an equivalent system, which will have the same capacity for storage of kinetic and potential energy. A mathematical explanation of the procedure used in reducing a pumping system to equivalent mass, and equivalent elastic systems, followed by calculations of typical elements of the system and examples illustrating specific applications of the method, are given.

THE changes which have taken place in the oil-producing industry during the last few years have greatly altered the general equipment program. The low producing rates, imposed by proration requirements, and the increased difficulties of making a profit, together with the future uncertainties of the industry have made it necessary to watch the investment cost of a well. This has resulted in using as light equipment as possible. While such equipment, when used within its range, will operate as well as heavy equipment when operated at its capacity, there is a general tendency toward making the lighter equipment do as much as the heavier. The result of this general tendency is to cause the smaller equipment either to be overloaded or the factor of safety to be reduced to a very small value. Under these conditions, every possible provision should be made to operate the equipment in such a manner as to keep the loads and stresses at a minimum. The loads can be controlled to some extent by using proper speeds, stroke, and plunger size. Proper counterbalancing will influence peak loads and stresses more than any other single item. The use of proper counterbalance can reduce the peak torque by about one half, that is, the effective capacity of the equipment will be reduced about one half, if counterbalance is not used.

As factors of safety have been decreased and every effort expended toward reducing investment and getting the most out of equipment, it has become increasingly necessary to eliminate or investigate every possible source of trouble. Among the sources are vibration or critical-speed problems in connection with the pumping system. Among the problems of this type which have been studied are the investigation of vibrations in sucker-rod strings (1, 2),[2] torsional vibrations in the gear-reduction system of pumping units (3), and investigations of the peak loads, resulting from the engine impulses (4). These investigations have covered various phases of this general problem. The results have indicated that, under certain conditions, the loads and stresses, resulting from critical or resonance speeds, could be of the same order of magnitude as the normal stresses.

Figs. 1, 2, and 3 show cases where these effects have been

measured. Fig. 1 shows the actual torque transmitted to a reduction gear by the engine, as measured by a torque dynamometer mounted in the driving pulley on the gear reducer. The engine explosions can be clearly seen on this diagram, and the impulses resulting from them are an appreciable percentage of the peak torque. The peak in this case would have been doubled had no counterbalance been used. Fig. 2 shows the torque obtained for a case where a higher-speed engine was used to drive only a counterbalance. A severe vibration occurred in this case as a result of the firing of the engine when the torque was a maximum. Fig. 3 shows a case where large vibrations in resonance with engine explosions were set up. In this case, the peaks of the vibrations are about twice the normal torque requirements. Another serious effect of such vibrations is also shown, i.e., the oscillation of the torque back and forth across the zero-torque line. When the torque is positive (above the line), the engine is driving the sucker rods. When the torque is negative (below the line), the rods are driving the engine. When the zero line is crossed backlash in the gears is taken up, resulting in impact stresses on the gears. This condition results in an increase in the number and magnitude of impacts, and as wear occurs this becomes more serious. It may account for wear or pitting on the back side of gear teeth when the normal load is always in one direction.

General Methods Used

The mathematical solution of certain types of vibration problems has received much attention and covers many types of engineering problems (5, 6, 7, 8). However, as is typical of many

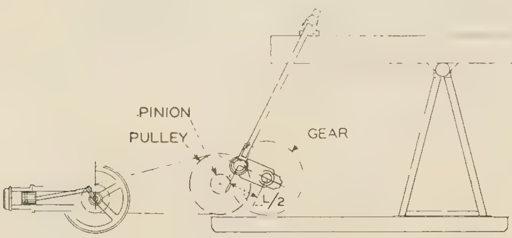

Fig. 4 Schematic Arrangement of Pumping-Unit System

engineering problems, certain types of elastic systems do not readily lend themselves to analytical solutions because of the involved nature of the problem, rather than the problem's not being adaptable to mathematical analysis. The system to be discussed in this paper comes under this latter heading so that some method of approach other than the purely mathematical one is necessary.

The natural vibrations of elastic systems involve the interchange of potential and kinetic energy. The potential energy in the system is present as elastic energy stored in the shafts or other elastic members. The kinetic energy is stored in the weight or mass of the system due to its velocity. Any system, therefore, must have elasticity and mass to be able to vibrate. As an example of such systems might be mentioned a weight on a spring where the weight is the mass of the system in which kinetic energy may be stored, and the spring is the elastic member where potential energy may be stored. The solutions of the more complicated types of vibration problems are based on the principle of replacing a complicated system by an equivalent system which will have the same capacity for storage of kinetic and potential energy.

In a pumping-unit system, as has been shown schematically in Fig. 4, the various parts operate at different speeds and have different elastic properties and masses. In an equivalent system, all parts are reduced to an equivalent rotating system, and the masses and elastic members are then varied to give an equivalent energy system. In this system, all elastic members are reduced to an equivalent shaft of unit diameter and of such a length as to give an equivalent energy-storage capacity at engine speed. The masses are likewise determined to give an equivalent energy-storage capacity at engine speed. In cases of members having a variable mass, the equivalent mass necessary to give the same effect over a cycle will be used.

Standard Solutions

In the calculations to be made, there are three general types of vibrations to be considered which have been treated in detail in the literature. To simplify the treatment, only the formulas for these cases will be considered in this paper. The first of these is the case of the vibration of a weight hung on a spring, as shown in Fig. 5. The natural frequency of such a system, i.e., the frequency with which the system will vibrate if displaced from its normal position, is

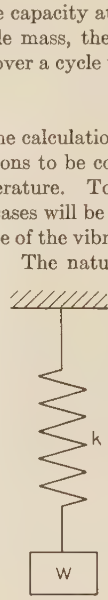

Fig. 5 Weight Suspended From Spring

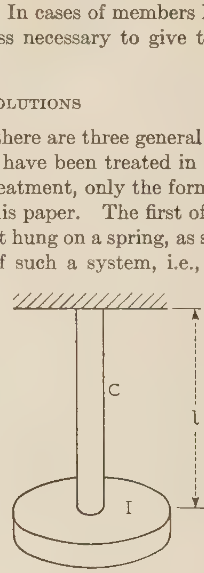

Fig. 6 Disk on End of Shaft

$$f = \frac{1}{2\pi}\sqrt{\frac{gk}{W}} \qquad [1]$$

if the mass of the spring is neglected.

Where f = natural frequency in vibrations per second
g = in. sec^{-2} = 386
W = weight, lb
k = spring const, lb per in.

A second type of problem is that of a disk on the end of a shaft as is indicated in Fig. 6. The natural frequency of such a system is

$$f = \frac{1}{2\pi}\sqrt{\frac{C}{I}} \qquad [2]$$

For a circular shaft of uniform cross section

$$C = \frac{E_s}{l} \times \frac{\pi d^4}{32} = \frac{E_s}{l} J \qquad [3]$$

where E_s = torsional modulus of elasticity, psi
l = length of shaft, in.
J = polar moment of inertia of shaft, in.^{4}
d = shaft diameter, in.
I = moment of inertia of disk, lb in. sec^2
C = torque required to produce unit angle of twist

The moment of inertia for a circular disk of uniform thickness can be expressed as

$$I = \frac{WD^2}{8g} \qquad [4]$$

where W = weight of disk, lb
D = diameter of disk, in.

In the case of a flywheel or pulley, the thickness is not uniform so that it is necessary to express the moment of inertia in terms of some calculated value. If it is assumed that the mass is concentrated in the rim, then

$$I = \frac{WD_r^2}{4g} \quad [5]$$

where D_r is the mean diameter of the rim in inches and g is 386 in. sec^{-2}.

If more exact calculations are made, taking into account the weight in the arms, hub, etc., the results are normally given as the sum of the individual WD^2 values for each part. In this case we have

$$I = \frac{\Sigma WD^2}{4g} = \frac{\Sigma Wr^2}{g} \quad [6]$$

where ΣWD^2 represents the sum of individual $W \times d^2$ values or ΣWr^2 represents the sum of the $W \times r^2$ values, where r is the radius of the weight W or of an element of weight W.

In all of the cases cited, the mass of the shaft has been neglected. Regardless of how the mass of the disk is expressed, the frequency can be calculated from Equation [2] by substituting the proper value for I.

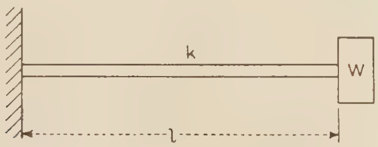

Fig. 7 Weight on End of Fixed Beam

The third case to be considered is that of a weight mounted on the end of a fixed beam as shown in Fig. 7. In this case, the spring constant k must be determined from the deflection characteristics of the beam. The beam deflection is given by

$$S = \frac{Wl^3}{3EI_b} \quad [7]$$

where S = beam deflection, in.
W = weight on end of beam, lb
E = modulus of elasticity, psi
I_b = moment of inertia of beam section, in.^{4}
k = spring constant of beam

$$k = \frac{W}{S} = \frac{3EI_b}{l^3} \quad [8]$$

Equivalent-Mass Systems

It is necessary to reduce the complicated pumping system, shown in Fig. 4, to an equivalent system in order to determine the vibration characteristics of the system. The various rotating masses in the system operate at different speeds, and some of the masses, as in the case of the sucker rods, beam counterbalance, and engine piston, have motion of translation or have an oscillating motion instead of fixed rotation so that some method of converting these into equivalent rotating masses is necessary. The general principle, in reducing these various mass systems to an equivalent simple rotating system, is to make the conversion on the basis of equivalent kinetic-energy storage capacity.

The simplest of the cases involved is that existing in a speed reducer. This case is shown schematically in Fig. 8. Fig. 8(a) shows the actual gear train and Fig. 8(b) shows the reduced system. Let N_1 be the speed of masses i_1 and i_2, and N_2 be the speed of masses i_3 and i_4. In reducing the mass i_3 to an equivalent at the speed of shaft 1, it will be necessary to multiply i_3 by the square of the speed ratio, since the kinetic energy of the mass will vary as the square of angular velocity or speed. Since the elasticity of the gear teeth is negligible, compared with the shaft elasticity, mass i_2 and the reduced mass of i_3 will combine directly to give mass I_2. On the foregoing basis, we will have for the equivalent masses of this system

$$I_1 = i_1$$

$$I_2 = i_2 + \frac{N_2^2}{N_1^2} i_3$$

$$I_3 = i_4 \frac{N_2^2}{N_1^2}$$

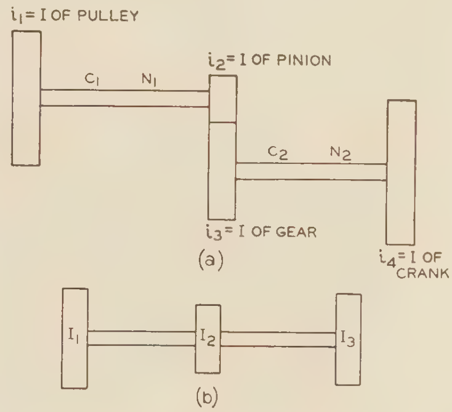

Fig. 8 Schematic Diagram of Speed Reducer

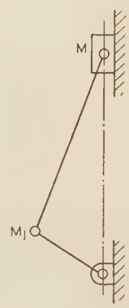

Fig. 9 Slider Crank

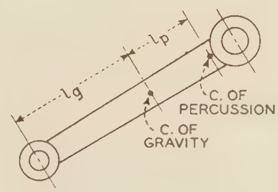

Fig. 10 Connecting-Rod System

In general, the equivalent inertia of masses having rotary motion will be given by

$$I \text{ equivalent} = \frac{(\text{Speed of actual mass})^2}{(\text{Speed of equivalent mass})^2} \times I \text{ actual} \quad [9]$$

By using this formula, it is possible to reduce the mass directly to the required speed. In this paper, all masses will be reduced to the engine speed so that the term (speed of equivalent mass) will be the speed of the engine. This general formula applies regardless of the method of driving the mass, i.e., through gear, belt, or chain.

In the case of reciprocating masses, it is necessary to resort to approximations inasmuch as the actual systems become very difficult to solve mathematically. Under conditions considered, the approximations used will have little effect on the critical or resonant speeds. One case is the slider crank or engine mechanism shown in Fig. 9. This case has been treated by Timoshenko (5) who found that, for critical-speed calculations, the

weight or mass of this system can be replaced by an equivalent fixed mass at the crankshaft. As a first step in such a mass reduction, it is necessary to reduce the mass of the engine connecting rod with its complicated motion to a simple system. It can be shown that for the connecting-rod system, Fig. 10, the mass of the connecting rod can be replaced by a mass at the piston wristpin or crosshead as the case may be, and another mass at the center of percussion with respect to the wristpin axis. It is obvious that such a system does not simplify this particular problem. If this center of percussion is close to the crankpin center, the mass can be used at the crank center with sufficient accuracy. While this is obviously an approximation it will be used as the basis for reduction in this case. With this approximation we have

$$M_1 = \frac{l_g}{l_g + l_p} M$$

and

$$M_2 = \frac{l_p}{l_g + l_p} M$$

where M = mass of connecting rod
M_1 = mass of connecting rod concentrated at crankpin
M_2 = mass of connecting rod concentrated at wristpin
l_g = distance between wristpin and center of gravity, in.
l_p = distance between center of gravity and center of percussion, in.

After the connecting-rod mass has been concentrated at the wristpin and crankpin, it is necessary to convert the piston-mass

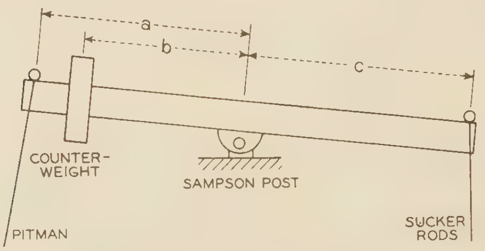

Fig. 11 Beam Counterbalance

and connecting-rod-mass component at the wristpin to an equivalent mass or inertia at the crankpin. Timoshenko (5) shows that the mass or inertia of a disk which, concentrated at the crankshaft, will give the same kinetic-energy effect is

$$I_e = \left[M_1 + \tfrac{1}{2}(M_2 + M_p) \left(1 + \frac{r^2}{4l^2}\right)\right] r^2 \ldots\ldots [10]$$

where M_1 and M_2 are as given.

M_p = mass of piston and crosshead = $\frac{W_p}{g}$
r = crank throw, in.
l = length of connecting rod, in.
I_e = engine-parts inertia

Since for the cases considered $\frac{r}{l}$ is small, the term $\frac{r^2}{4l^2}$ will be negligible so that, for most cases, the equivalent moment of inertia will be given by

$$I_e = [M_1 + \tfrac{1}{2}(M_2 + M_p)]r^2 \text{ (approx)} \ldots\ldots [11]$$

For the case of beam counterbalance, as shown in Fig. 11, the mass can be reduced to an equivalent mass or rotating disk at the crank if the elasticity of the pitman is neglected. Beam counterbalance will, therefore, be similar to a rotary counterbalance. In working out the reduced beam mass, it is assumed that the pitman bearing on the beam has reciprocating motion. The making of this assumption is equivalent to reducing the system to that shown in Fig. 9, provided the mass of the counterbalance is first reduced to the upper pitman bearing. This can be done by making the kinetic energy of the reduced mass equal to that of the original mass. For the data shown in Fig. 11 we have

$$M_{CB} = \frac{b^2}{a^2} M_c \ldots\ldots [12]$$

where M_{CB} = reduced mass of beam counterbalance
b = distance from walking-beam center to counterbalance center of gravity, in.
a = distance from walking-beam center to wristpin center, in.
M_c = actual counterbalance mass

The equivalent inertia at the crank center will be given by

$$I_c = \frac{M_{CB}}{2} \left(\frac{L}{2}\right)^2 \left(\frac{N_c}{N_1}\right)^2 \text{ (approx)} \ldots\ldots [13]$$

where $\frac{L}{2}$ = crank radius on pumping unit, in.
N_c = speed of crank or strokes per minute
I_C = equivalent counterbalance inertia, reduced to engine speed

The reduction of the sucker-rod-and-fluid system is somewhat more difficult. The sucker-rod system has sufficient length and elasticity so that it does not respond as a concentrated mass (2). The time required to transmit the motion is appreciable, and the fluid loading is intermittent so that any attempt to evaluate this system accurately is difficult. In order to arrive at a value which will serve as a basis to indicate the relative magnitude of the effect of the sucker rods on the system, it will be assumed that the integrated effect of the sucker-rod-and-fluid system will approximate that which would be obtained if the weight of the sucker rods were concentrated at the end of the walking beam. This amounts to saying that the loss of effectiveness of the sucker-rod mass, due to elasticity and time lag, is balanced by the intermittent effect of the fluid mass. On this basis, we would first reduce the sucker-rod weight at the walking beam to the pitman bearing on the basis of equivalent kinetic energy or inversely as the velocities squared. This mass would then be reduced, as is the beam counterbalance, giving

$$I_R = \frac{W_r}{2g} \left(\frac{c}{a}\right)^2 \left(\frac{L}{2}\right)^2 \left(\frac{N_c}{N_1}\right)^2 \text{ (approx)} \ldots\ldots [14]$$

where N_c, N_1, L are as before, c and a are as shown in Fig. 11, and W_r is the weight of sucker rods.

g = 386
I_r = effective inertia of rods at engine speed

A somewhat closer approximation of the sucker-rod-and-fluid system could be obtained by breaking the rod-and-fluid systems up into units of smaller mass and introducing elasticity between the small masses.

Equivalent Elastic Systems

The members in a system, such as shown in Fig. 4, store elastic or potential energy. Since the various shafts rotate at different speeds and since some of the members, such as the belt and walking beam, are nonrotating members, it is necessary to reduce the system to an equivalent system of shafts rotating at engine speed. The equivalent shaft system involves both diameter and

length, since they are both involved in determining the energy which can be stored. In order to simplify the problem, the shafts will all be reduced to a unit diameter which is a diameter of 1 in. The length is then determined to give the proper energy storage. The longer the equivalent shaft, the greater its energy-storing capacity.

If a unit diameter is used as a basis for calculation, it is necessary to vary the length, in order to maintain a constant c value or energy-storage capacity. This can be arrived at by referring to Equation [3] from which

$$C = \frac{E_s}{l} \cdot \frac{\pi d^4}{32}$$

If d is made unit diameter, and l_e denotes the equivalent length, we will have for a uniform shaft

$$\frac{E_s}{l} \times \frac{\pi d^4}{32} = \frac{E_s}{l_e} \times \frac{\pi \times 1^4}{32}$$

or

$$l_e = \frac{l}{d^4} \qquad [15]$$

For a shaft which varies in diameter between supports, it is necessary to find the equivalent lengths of the various sections and add them together to obtain the total equivalent length of a shaft of unit diameter.

In the case of the gear-reduction system, shown in Fig. 8, it is necessary to find the equivalent torsional-rigidity constant C of shaft 2 at the engine speed. This can be determined from the equation

$$C \text{ equivalent} = \frac{(\text{Speed of actual shaft})^2}{(\text{Speed of engine shaft})^2} C \text{ actual}$$

or

$$C_e = \left(\frac{N}{N_1}\right)^2 C \qquad [16]$$

where C_e = equivalent torsional rigidity of shaft
N = actual shaft speed
N_1 = engine-shaft speed
C = actual torsional rigidity of shaft

since

$$C_e = \frac{E_s}{l_e}\frac{\pi d_e^4}{32} = \frac{\pi E_s}{32 l_e} \text{ for } d_e = 1$$

and

$$C_e = \frac{\pi E_s}{32 l_e} = \left(\frac{N}{N_1}\right)^2 C = \left(\frac{N}{N_1}\right)^2 \frac{E_s}{l} \times \frac{\pi d^4}{32}$$

we have

$$l_e = \frac{l}{d^4} \times \left(\frac{N_1}{N}\right)^2 \qquad [17]$$

which is the equivalent length for a shaft of unit diameter, at engine speed N_1.

The crankshaft can be presented schematically, as is shown in Fig. 12. As can be seen from this diagram it is quite difficult to arrive at an equivalent length of such a shaft. Several exact formulas based on certain assumed conditions have been worked out by Timoshenko (5). A simplified empirical formula, as given by Carter, appears to be satisfactory for normal conditions and will be used here. Using the dimensions, as given in Fig. 12, this formula can be expressed in the following form if unit diameter is assumed for the equivalent shaft, l_{ec}

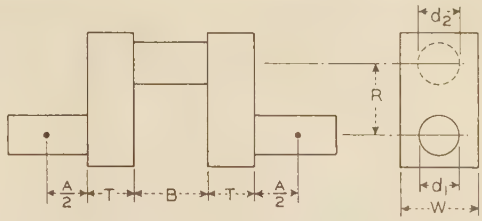

Fig. 12 Schematic Diagram of Crankshaft

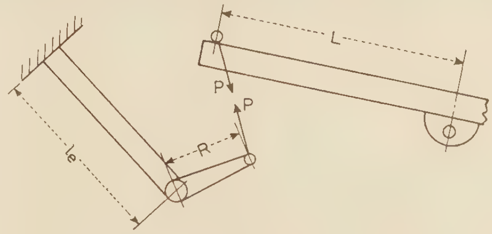

Fig. 13 System for Calculating Shaft Equivalent to Walking Beam

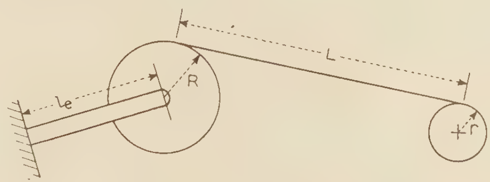

Fig. 14 Equivalent Diagram for Belt or Chain Drive

$$l_{ec} = \left(\frac{A + 0.8T}{d^4}\right) + \left(\frac{0.75B}{d_2^4}\right) + \left(\frac{1.5R}{TW^3}\right) \qquad [18]$$

The moment of inertia of the walking beam is negligible compared with the inertia of the other parts and will not be considered. This, however, does not mean that the elastic properties of the beam can be neglected. Fig. 13 shows schematically a system which will be used as a basis for calculating the equivalent shaft to have the same energy storage as the walking beam. If the beam and shaft be loaded as shown, the energy stored in the shaft is

$$U = \frac{1}{2}\frac{T^2 l_e}{E_s J} = \frac{1}{2}\frac{(PR)^2 l_e}{E_s J}$$

and that stored in the beam is

$$U = \frac{1}{6}\frac{(PL)^2 L}{EI}$$

If these are to be equal we then have

$$\frac{1}{2}\frac{(PR)^2 l_e}{E_s J} = \frac{1}{6}\frac{(PL)^2 L}{EI} \qquad [19]$$

From which we find

$$l_e = \frac{1}{3}\frac{L^3}{R^2} \times \frac{E_s J}{EI} \qquad [20]$$

Actually the elastic members from the crank on are effective only about one half the time. This same condition was true for the masses, and it was shown that the beam weights and the sucker rods were effective only one half the time, so that the value of the equivalent mass is only one half of the actual mass. An-

other manner of considering this problem is to note that the natural frequency of any system is a function only of the ratio of C to I. If then the mass in one part of the system is reduced, the C value will likewise have to be reduced. On this basis we have

$$l_e = \frac{1}{6}\frac{L^3}{R^2}\frac{E_sJ}{EI}$$

Fig. 14 shows an equivalent diagram for a belt or chain drive. In this case the belt tension P represents only the effective pull. It is assumed that the slack-side tension does not influence the problem since it supposedly puts a constant stress or energy into the system. The energy stored in the belt will be given by

$$U = \frac{1}{2}\frac{P^2L}{AE_B}$$

and in the shaft

$$U = \frac{T^2l_e}{2E_sJ} = \frac{(PR)^2l_e}{2E_sJ}$$

Equating these and solving for l_e we have

$$l_e = L \times \frac{E_s}{E_B}\frac{J}{AR^2}$$

For a shaft of unit diameter this reduces to

$$l_e = \frac{\pi L}{32A} \times \frac{E_s}{E_B}\frac{1}{R^2} \qquad [21]$$

Fig. 15 shows a plot of data obtained from a belt test. These data show that, after the initial stretch is taken up, the modulus

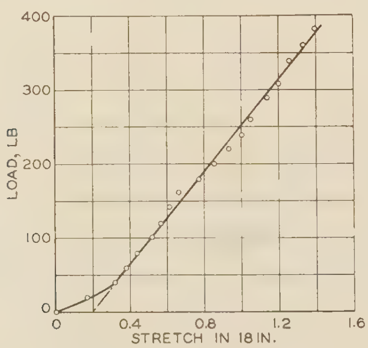

Fig. 15 Data From Belt Test

(4-ply rubber belt; 1 in. wide × 0.23 in. thick; breaking load 1200 lb; permanent stretch at B.P. = 1/2 in. in 18 in., Et = 22,640; stress at rupture 5454 psi.)

of elasticity for the rubber belt E_b = 22,600 psi. They will be used in determining the equivalent shaft length for a belt.

The reduction of the sucker-rod string to an elastic system, composed of several masses with elastic members in between, could be made using the same general formula. It would be necessary to reduce the sucker-rod system to the pitman and again take one half the value as was done in the case of the walking beam.

Torsional Vibration of Walking Beam

In addition to the conditions considered, it is possible for a walking beam carrying beam weights to have a torsional vibration. Under these conditions it would vibrate in a manner similar to the shaft and disk shown in Fig. 6, the inertia in this case being the inertia of the beam weights with respect to the longitudinal axis of the beam and the spring constant being the torque required to produce unit angle of twist in the beam. The calculation of the spring constant c of this system is complicated by the fact that the angle of twist and the stresses are not a function of the polar moment of inertia as used for circular shafting. Timoshenko (5) gives the following formula as an approximation to the angle of twist in an I-beam section subject to a torque T, where the dimensions are as shown in Fig. 16

$$\theta = \frac{3T}{(b_1c_1^3 + 2b_2c_2^3)E_s}$$

Since the spring constant $c = \frac{I}{\theta}$ we have

$$C = \frac{(b_1c_1^3 + 2b_2c_2^3)E_s}{3}$$

The shearing stress in a walking beam (not including stress concentration at re-entrant corners) is given by

$$S_s = \frac{3TC_2}{(b_1c_1^3 + 2b_2c_2^3)}$$

Since beam weights are generally rectangular in shape, their polar moment of inertia can be calculated approximately by the following formula (using dimensions as given in Fig. 17)

$$I_p = \frac{Wdt(d^2 + W^2)}{1065}$$

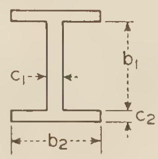

Fig. 16 I-Beam Section

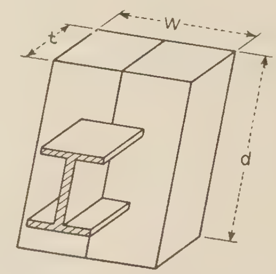

Fig. 17 Dimension for Rectangular Weight

As an example, consider a 24-in. 100-lb I-beam, having a beam weight with t = 50, W = 20, d = 40 situated 80 in. from the sampson-post bearing. For these values, we would find that, in round numbers

$$I_p = 75{,}000$$

$$C = 1 \times 10^6$$

and finally the frequency

$$f = \frac{1}{2\pi}\sqrt{\frac{1 \times 10^6}{75{,}000}} = 0.49 \text{ per sec} = 29 \text{ per min}$$

A 15-in. 55-lb beam with 6 weights 15 × 30 × 6 in. situated 90 in. out from the beam support would have a natural frequency of about 40 cycles per min.

In each of these cases, the natural frequency is close to the normal operating speeds. The magnitude of the natural frequency will vary with the location and magnitude of the weights. The point at which to consider the weights located will depend upon the method of anchoring the weights to the beam and may be difficult to determine.

Since the torque which may be safely carried by a beam is relatively small, it would not take a very large vibration to result in quite high stresses. A torsional vibration superimposed on a heavily loaded beam could result in an increase of stresses to the point where failure might ensue.

TABLE 1 DATA FOR PUMPING UNITS, WITH SUMMARY OF EQUIVALENT MOMENTS OF INERTIA AND ELASTICITIES

	Single cylinder		Four cylinder

CALCULATION OF TYPICAL ELEMENTS

The critical speeds in a pumping-unit system will be dependent upon the specific values of the sizes and weight of the many parts. Each case will have its own critical speeds and should, therefore, be analyzed separately.

A typical pumping unit can, however, be used to illustrate the method of solving for critical speeds and give some indication as to the relative importance of the various parts in the vibrating system. Two pumping units were selected, one with a single-cylinder and the other with a four-cylinder engine. The data for both cases, with a summary of the equivalent moments of inertia and elasticities, are given in Table 1.

The following examples should illustrate the methods used to calculate the equivalent elasticities. On the crankshaft in Fig. 18, the equivalent length from the flywheel to point B is, by Equation [15]

$$l_{ab} = \frac{7^1/_2}{(3^1/_2)^4} = 0.050 \text{ in.}$$

Since the equivalent shaft will be considered as rotating at engine speed, there is no correction for speed. The equivalent length between point B and the center of the main bearing C is found in like manner and added to l_{ab} to give the equivalent length of the unit diameter shaft. Section C-E is the crank. Using Carter's formula

$$l_{ce} = \frac{2 \times 1^3/_8 + 0.8 \times 2}{(4^3/_4)^4} + \frac{0.75 \times 3^3/_4}{(4^1/_2)^4} + \frac{1.5 \times 4^1/_2}{2 \times 6^3}$$

$$= 0.031 \text{ in.}$$

One half of this added to l_{ac} gives the equivalent length between the flywheel and the crank.

The equivalent length of the pinion shaft, Fig. 20, is

$$l_p = \frac{7}{(2^1/_2)^4} = 0.179 \text{ in.}$$

This length is at the pinion-shaft speed so must be corrected to engine speed, giving

$$l_{p1} = 0.179 \times \left(\frac{600}{200}\right)^2 = 1.61 \text{ in.}$$

The equivalent length of the belt is based on Equation [21].

$$l_{\text{belt}} = \frac{\pi \times 60}{32 \times 0.3 \times 8} \times \frac{12{,}000{,}000}{22{,}600} \times \frac{1}{(5)^2} = 52 \text{ in.}$$

This length is based on the engine-pulley radius so no correction is necessary.

The equivalent length of the beam is based on Equation [20].

$$l_{\text{beam}} = \frac{1}{6} \times \frac{2(7 \times 12)^3}{20^2} \times \frac{12{,}000{,}000}{30{,}000{,}000} \times \frac{\frac{\pi(1)^4}{32}}{509} = 0.04 \text{ in.}$$

The moment of inertia of the beam cross section is 509 in.^{4} The value of l_{beam} must be corrected for speed.

$$l_{\text{beam}} = 0.04 \times \left(\frac{600}{20}\right)^2 = 36 \text{ in.}$$

After all the mass moments of inertia have been calculated, they must be corrected to engine speed. The rotary-counterbalance mass moment of inertia about the crank was found to be 9350 lb in. sec^2 at a crank speed of 20 rpm, therefore

$$I_{cb} = 9350 \times \left(\frac{20}{600}\right)^2 = 10.4 \text{ lb in. sec}^2$$

Summary

An analysis of the cases outlined in the previous section shows that the belt elasticity and the moment of inertia of the engine flywheel are the two outstanding parts of the system. The sucker rods and counterbalance are not nearly as effective as the lighter engine flywheel because of their slow speed.

The entire system may be closely approximated by a two-mass system since the equivalent length of the belt is long when compared to the lengths of the other equivalent lengths. The general formula for solving a two-mass system is

$$N = \frac{60}{2\pi}\sqrt{\frac{\pi E_s d^4(I_1 + I_2)}{32 I_1 I_2 l}}$$

where N = vibrations per min
d = diameter of shaft, in.
I_1 = moment of inertia of one mass, lb in. sec^2
I_2 = moment of inertia of second mass, lb in. sec^2
l = length of shaft, in.

With this approximation, the critical speed of the single-cylinder unit with rotary counterbalance becomes

$$N = \frac{60}{2\pi}\sqrt{\frac{\pi \times 12{,}000{,}000 \times 1^4(943 + 23)}{32(943)\,(23)\,52}} = 304 \text{ rpm}$$

Table 2 gives the remaining critical speeds calculated.

TABLE 2 CRITICAL SPEEDS

	Critical speeds, rpm: Rotary balance	Critical speeds, rpm: Beam balance
Single cylinder	304	364
Four cylinder	354	393

These values indicate that pumping units do operate at values near the critical speed. Naturally, these speeds must be watched and kept a safe distance (20 to 30 per cent) from this critical speed.

To make a further analysis of the problem, the two ends of the complete unit may be analyzed individually without introducing any appreciable error. The belt is the elastic member separating the two ends.

In solving for the critical speeds of the pumping end of the system, it is to be noticed that there are four masses to be considered. However, the mass of the gears is very small and also relatively close to the mass of the pulley. Therefore, the mass of the pulley and the mass of the gears may be considered as one for most practical purposes. This assumption greatly simplifies the solution of the problem. The usual equation for solving three-mass systems is

$$\left(\frac{I_1I_2I_3}{k_1k_2}\right)\omega^4 - \left(\frac{I_1I_2 + I_1I_3}{k_1} + \frac{I_2I_3 + I_1I_3}{k_2}\right)\omega^2 + (I_1 + I_2 + I_3) = 0$$

where I = moments of inertia, lb in. sec^2

$$k = \frac{E_s}{l_e} \times \frac{\pi d^4}{32}$$

$$\omega = \text{radians per sec}$$

The critical points for the single-cylinder pumping unit with the rotary counterbalance are determined as follows

$$I_1 + I_2 + I_3 = 22.7$$

$$k_1 = \frac{12{,}000{,}000 \times \pi}{22.8 \times 32} = 51{,}600$$

$$k_2 = 32{,}700$$

$$\frac{I_1I_2}{k_1} = \frac{8.1 \times 10.4}{51{,}600} = 0.00163$$

$$\frac{I_1I_3}{k_2} = \frac{8.1 \times 4.2}{51{,}600} = 0.00066$$

$$\frac{I_1I_3}{k_2} = \frac{8.1 \times 4.2}{32{,}700} = 0.00104$$

$$\frac{I_2I_3}{k_2} = \frac{10.4 \times 4.2}{32{,}700} = 0.00134$$

$$\frac{I_1I_2I_3}{k_1k_2}\omega^4 = \frac{8.1 \times 10.4 \times 4.2}{51{,}600 \times 32{,}700}\omega^4 = 0.00000021\omega^4$$

so $0.00000021\omega^4 - 0.00467\omega^2 + 22.7 = 0$

Solving by the quadratic equation

$$\omega^2 = 7220 \text{ or } 15000$$

$$\omega = 85 \text{ or } 122.5 \text{ radians per sec}$$

$$N_1 = \frac{122.5 \times 60}{2\pi} = 1170 \text{ rpm}$$

$$N_2 = \frac{85 \times 60}{2\pi} = 812 \text{ rpm}$$

The critical speeds for the other counterweights are given in Table 3.

TABLE 3 CRITICAL SPEEDS FOR COUNTERWEIGHTS

	Critical speeds, rpm	
Single cylinder		
Rotary balance	812	1170
Beam balance	808	1680
Zero balance	815	....
Four cylinder		
Rotary balance	680	1130
Beam balance	740	1680
Zero balance	755	....

A general study of these values indicates

1 That the second critical speed is of the same order of magnitude as the engine speed.

2 That the belt and engine flywheel are the largest items involved, and any change in their values may greatly affect the critical speed.

The fact that the various critical speeds are within the normal operating ranges for oil-well pumping conditions and the fact that the actual measured torque cards show the presence of such vibrations indicate that further study of this problem may be desirable. The presence of damped resonance vibrations may result in high gear-tooth and belt loads so any method of eliminating them will permit operation of equipment with a lower factor of safety or at a higher rating. Further work is contemplated on the study of the effect of engine explosions on the peak torque transmitted to gear teeth and the effect of this peak on rating formulas.

Discussion

Eugene Hosford.[3] There have been various fundamental rules established for the selection of a pumping unit and engine, but in the past there seems to have been very little attention given to the speed at which the equipment should be operated. The general rule is to operate the unit at a speed which will pump the required amount of fluid. In this paper, the authors have shown that the critical speed of certain pumping systems can occur at normal operating speeds. Certainly, such operating speeds should be avoided if at all possible. The A.P.I. peak-torque rating of gears may be sufficiently high to allow for a reasonable increase in torque due to vibration without failure of the gears, but it is of real importance that this paper present a definite method of determining at which speeds the torque may be the highest. Before the formulas included in this paper can be accurately used for calculating torque on the gears, an evaluation of the effect of engine explosions must be made. It is fortunate that such an investigation is planned by the authors of this paper.

J. C. Slonneger.[4] The dominating masses in an oil-well pumping system are the engine flywheel (or flywheels), counterweight, and unit drive sheave, in the order named. The elastic system is primarily made up of the belt drive, the unit shaft, and, in the case of engines having a flywheel on the outer end, the crankshaft of the engine. All other masses and elastic members may be neglected in ordinary calculations for the purpose of predicting critical speeds. By comparing exact calculations with the foregoing assumption, it has been found that the difference in calculations is 3 per cent or less.

In making calculations it is usually more convenient to reduce the system to the high-speed shaft of the unit. In this way it is rather simple to compare various belt drives and engines on any given pumper. The authors have reduced the system to the engine shaft.

Single-noded vibrations are most bothersome to slow-speed engines. It should be remembered that the amplitude of any vibration is a function of the disturbing force, which in this case is a function of cyclical variation. The tuning of systems for this type of engine should be such that if criticals cannot be completely avoided, they should be chosen at the top of the engine speed range where the cyclical variation is smallest.

On the other hand, with multicylinder engines, single-noded vibrations usually have a frequency lower than that of the disturbing force, and therefore are harmless. However, the frequency of two-noded vibrations is very troublesome here in avoiding synchronism. The unit sheave because of its speed often has as much torsional inertia as the counterweight and dominates the two-noded vibrations. A study shows that two-noded vibrations are little influenced by the belt resilience because of the small amplitude of the flywheel, and also because the frequency is a function of the square root of the resilience. In V-belt drives, usually used with multicylinder engines, evidence of critical speeds is given by violent vibration of the belts.

Timoshenko's method of reducing a reciprocating mass to a rotary mass is applicable only in cases where the frequency of the disturbing force is equal to or less than the frequency of reciprocation. This applies to crankshafts of engines but not to a beam counterbalance. The disturbing force is usually more than 4 times as rapid as the reciprocating motion of the beam counterbalance; in some cases, it is as much as 150 times as rapid. The effect of the beam counterbalance is to change continuously the frequency of the system as its effectiveness changes with the crank angle. This is evidenced in the authors' Fig. 2. The variation in amplitude is due entirely to the system's falling in and out of synchronism from the causes just cited. Note that, in Fig. 1, the amplitude of vibration remains nearly constant since this is a rotary balance having constant tuning.

Authors' Closure

Mr. Slonneger has given a very concise discussion of the interpretation and application of vibration phenomena as applied to oil-well pumping systems. The authors have corrected an error in the preprint which Mr. Slonneger called to their attention. The approximations which he has suggested greatly simplify the solution of such problems. There is, however, danger from over-simplification; and each type of problem must be considered separately. As is indicated in Fig. 22 for example, the sucker rods may be as important as the rotary balance. The example shown in Fig. 2 is for a rotary counterbalance and not a beam balance as Mr. Slonneger infers.

The method of solution offered in the main paper is intended only as an approximation. To illustrate the accuracy to be expected, the critical speeds for a four-mass system are given in Table 4. These results are as accurate as any data that might be used. They show that the accuracy is much better when

TABLE 4 CRITICAL SPEEDS BASED ON A FOUR-MASS SYSTEM

	Critical speeds		
Single cylinder			
Rotary balance	325	774	1140
Beam balance	372	783	1660
Four cylinder			
Rotary balance	277	878	1230
Beam balance	344	878	1730

[3] Mechanical Engineer, Gulf Oil Corporation, Tulsa, Okla.

[4] Assistant Chief Engineer, The Continental Supply Company, Dallas, Texas.

the inertia of the engine and flywheel is great compared to the other elements. The results for the four-cylinder engine as determined by the approximate method are not in as good agreement as those of the single-cylinder.

The exact solution for the critical speeds of a four-mass system can be determined from the following equation. The use of this equation eliminates the necessity of making some of the approximations which Mr. Slonneger suggests or the approximations the authors made.

$$-w^6\frac{I_1I_2I_3I_4}{k_1k_2k_3} + w^4\left\{\frac{(I_1+I_2)I_3I_4}{k_2k_3} + \frac{(I_2+I_3)I_1I_4}{k_1k_3} + \frac{(I_3+I_4)I_1I_2}{k_1k_2}\right\} - w^2\left\{\frac{(I_1+I_2+I_3)I_4}{k_3} + \frac{(I_1+I_2)(I_3+I_4)}{k_2} + \frac{(I_2+I_3+I_4)I_1}{k_1}\right\} + I_1+I_2+I_3+I_4 = 0$$

The authors appreciate the helpful suggestions and comments offered by Messrs. Hosford and Slonneger. It is hoped that further work along the lines suggested by Mr. Hosford will be possible in the near future.

Air-Heater Facts: 1926–1941

By E. L. HOPPING[1] and D. F. SCHICK, JR.,[2] PHILADELPHIA, PA.

In 1926, data were presented by N. E. Funk covering several types of air heaters used on boilers equipped with economizers and on some not so equipped. The equipment selected for discussion at the Chester and Richmond Stations of the Philadelphia Electric Company was relatively new at the time, but provided a valuable basis for future selection of air-heater units. The present paper gives facts pertaining to experience gained in operation of the air heaters previously mentioned; applications of new heaters to recently installed generating equipment; applications in associated industries; and trends evident in an analysis of new units. Further detail is given covering the selection of air heaters, corrosion problems, methods of eliminating corrosion, cleaning air-heater units, and troubles experienced with air-heater installations.

In a paper[3] before this Society in 1926, N. E. Funk presented comparative data on several types of air heaters used on boilers equipped with economizers and on others not so equipped. Tubular, plate, and regenerative air heaters were used. Experience was confined to tests on relatively new equipment at the Chester, Delaware, and Richmond Stations of the Philadelphia Electric Company. The data presented for the various arrangements of air heaters provided a valuable reference source for the future selection of air-heater units.

The present paper gives facts pertaining to experience with the air heaters discussed in the original paper, applications of heaters with more recently installed generating equipment, a brief summary of air-heater applications in associated industries, and the trends evident in an analysis of new units.

References made to specific stations are those of the Philadelphia Electric Company.

Air heaters are generally classified in two groups, i.e., the recuperative, those which transfer heat through a partition, continuously heating the cool side by conductive transfer from the hot; and the regenerative, those which alternately heat and cool the same mass, regenerating it thermally by passing hot gas over its surface.

The recuperative type includes the plate air heater composed of alternately spaced plates for air and gas passage, and the tubular air heater composed of a nest of tubes with the gas usually passing through the tubes.

Regenerative heaters may be stationary multichambered heating elements provided with dampers to alternate the gas-air flow. Usually, however, they are of the rotating heating element type, such as Ljungström air-heater units.

Selection of Air Heater

Studies dealing with the air heater are primarily economic. For each British thermal unit received from the flue gases by the air for combustion, there is a like decrease of heat to be supplied by the fuel in heating the air to furnace temperature. Capitalization of the annual fuel saving, debited by additional cost of fans and fan-power requirements, represents a theoretical maximum that can be spent for an air heater.

Practically the most economic proportioning of heating surface leads to the selection of the largest-size air heater possible. The air heater offers a low-temperature heat-absorbing surface, making it possible to obtain high thermal efficiency. Air-heater surface is relatively low-cost surface in contrast to the pressure parts of a boiler unit. A limiting factor for maximum surface is temperature. The gas temperature cannot be carried too low because of sulphur corrosion when the temperature of the gas approaches the dew point for the sulphur in the fuel, while the maximum air temperature is limited by firing conditions. Within such limits lie the proper proportioning of air-heater and economizer surface.

Corrosion of air heaters is primarily brought about by lowering the flue-gas temperatures below the dew point of the acid constituents of the flue gas. The outgoing flue gas should not be lowered to such an extent that the metal temperature of the air heater approximates the dew point. In all probability, the rate of corrosion would be greatest at the temperature of the dew point because of the combined action of the acid film and of substances brought into solution. The dew point, as previous investigators have indicated, is higher than appears from the moisture content alone, especially because of the presence of sulphur compounds in the gas. On account of the high boiling point of sulphuric acid, a trace of this vapor in the flue gas is sufficient to cause a high dew point. The corroding agents in the soot and fly ash in the gas accelerate this action. In the following discussion of corrosion, a limiting factor for metal temperature is indicated to be the fuel composition.

The outgoing-air temperature is another limiting factor. Here, the type of firing limits the temperature to which the air can be heated. Stoker firing limits the air temperatures to 300 to 400 F, because of stoker maintenance, while pulverized fuels, oil, and gas allow considerably higher air temperatures of 500 to 600 F.

An additional margin of safety is desirable because of the inability to secure even distribution of gas over all air-heater surfaces, particularly at low loads, resulting in certain areas having temperatures below the average.

Additional factors of space requirements, draft losses in the air and gas passages, ease of cleaning and repair, are a few other items to be evaluated before making final selection of the air heater.

Corrosion

An investigation made by The Babcock & Wilcox Company, relative to external corrosion of economizers and one which would be equally applicable to air heaters, indicates the possibility of corrosion according to the relation between metal temperatures and the sulphur content of the fuels.

The information obtained was from operating data and observation of the equipment on various installations, with respect to the presence or absence of attack on the tubes. It was further indicated that an exact relationship could not be established since other conditions, such as moisture in the fuel, are a part of the problem. However, these other variable factors approximate an average for the normal range of fuels, leaving sulphur as an index of the corrosion probability.

[3] "Comparative Performance of Air Preheaters," by N. E. Funk, Trans. A.S.M.E., vol. 48, 1926, pp. 337–356.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Kansas City, Mo., June 16–19, 1941, of The American Society of Mechanical Engineers.

When burning pulverized coal, the limiting range between no active corrosion and active corrosion appeared to be a metal temperature of approximately 160 F with 2 per cent by weight of sulphur in the coal, extending to 250 F with 5 per cent by weight of sulphur in the coal.

Burning coal on a stoker indicated the desirability of maintaining somewhat higher gas-outlet temperatures to avoid corrosion through the same sulphur range. With pulverized fuel, the combustion of the carbon and the sulphur is more complete and, consequently, the chance for formation of scale is less than when coal is burned on a stoker. A report[4] of an investigation by the Engineering Experiment Station, University of Illinois, supports this observation.

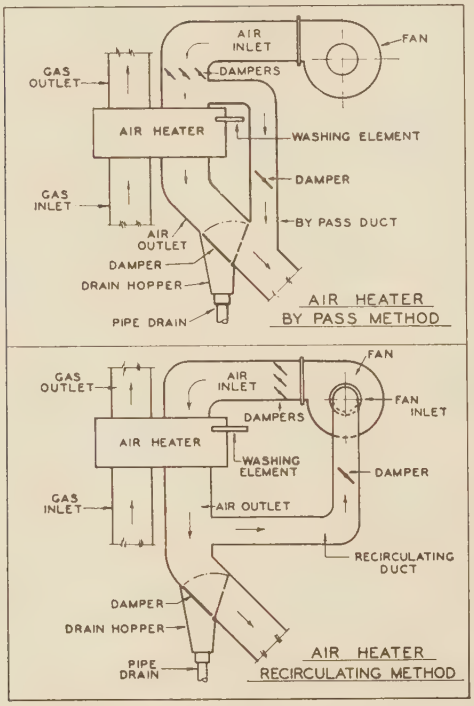

Fig. 1 By-Pass Method and Recirculating Method of Preventing Corrosion of Air Heaters

The results of the combustion of the sulphur in coal are not definitely known. Investigators assume, however, that for the most part the sulphur oxidizes to sulphur dioxide in the furnace. Then, as the colder portions of the system are reached, this gas is further partially oxidized to sulphur trioxide.

Prevention of Corrosion by By-Pass and Other Means

Since corrosion of air heaters, due to condensation of moisture carried by the flue gas, is most likely to occur at low ratings on the boiler, some simplified by-pass schemes are of value.

One of the most simplified schemes provides for a direct air by-pass duct for the air heater. This by-pass around the unit lowers the air-gas ratio and, therefore, increases the air temperature through the air heater and raises its metal temperature because of reduced heat transfer.

Another arrangement provides for recirculating the air. Air ducts are arranged so that some of the air discharged from the air heater returns to the inlet of the forced-draft fan. This arrangement increases the temperature of the entering air and raises the metal temperatures at the cold end. It is also possible to use a separate fan for recirculation.

Fig. 1 shows two arrangements as applied to the regenerative type of air heater. Similar arrangements are readily adaptable to the tubular-type air heater.

Where air heaters are operating under severe corrosion conditions special materials are used for the heating elements. Elements of varying depth on the cold end of Ljungström units are made replaceable and of special alloy. Corrosion tests show increased life with elements of Toncan iron and zinc-coated steel with only slightly increased initial cost. In other cases, heavier-gage tubes or heavier-gage elements are initially installed for tubular and regenerative units.

On pulverized-fuel-fired boilers at the Richmond and Schuylkill Stations of the Philadelphia Electric Company, provision has been made to by-pass Ljungström air heaters. The forced-draft fans are located above the air heaters. The by-pass duct takes a portion of cold air at the discharge of the fan and delivers the cold air to the warm-air-discharge side of the air heater. When outlet gas temperatures fall to 300 F, the by-pass duct is opened. This lowers the air-gas ratio, and outlet-flue-gas temperatures are raised to 300 F or higher. It is assumed that negligible corrosion will exist on the units above 300 F and, with this procedure, satisfactory corrosion experience has been the result. The Richmond air heaters have been in operation since 1935, and the Schuylkill units since 1938.

Limited experience when burning fuel oil in the Schuylkill boilers has not indicated any special problem, however, the sulphur content of this fuel oil was under 1 per cent.

The recirculating method has been installed with Ljungström units on pulverized-fuel-fired boilers at the Chester Station of the same company, but these units have only recently gone into operation. This method takes warm air, discharged from the air heater, and returns it to the inlet of the forced-draft fan. While the kilowatthour input to the forced-draft fan will increase during recirculation, this will occur only at low-load periods and does not increase the cost of fan or the normal power requirements. The increased air temperature to the boiler during this period may be a compensating item. The temperature of the air-heater elements should be increased, but whether the increase is substantial and formation of moisture and flue-dust corrosion will be eliminated remain to be determined after a period of longer operation and observation.

By means of the arrangements of duct work mentioned, an attempt is made to establish a relationship between condensation temperature and corrosion. In preventing the formation of a film of sulphuric acid on the metal, the temperature of the metal seems to be more important than that of the temperature of the gas or the air. The temperature of the gases may be well above the dew point, however, the metal may be below the dew point, due to the cooling effect of the cold forced-draft air.

Experience by the authors' company indicates that the tendency to clog tubes or air-heater sections, operating with stoker-fired boilers, is more likely than with pulverized-fuel-fired boilers. Since corrosion usually starts in clogged areas, the hazard then is greater with the stoker-fired boilers. As previously mentioned, this can be attributed to the fact that with pulverized fuel the combustion of the carbon and the sulphur in the coal is more complete.

Two Ljungström air heaters, installed at the Chester Station in 1925, and operating with a stoker-fired boiler, have required considerable maintenance of plates due to corrosion. This is in direct contrast to the very favorable, although shorter, experience with similar equipment on the pulverized-fuel-fired boilers previously mentioned.

[4] "The Corrosion of Power Plant Equipment by Flue Gases," by H. F. Johnstone, University of Illinois, Engineering Experiment Station, Bulletin No. 228, 1931.

Cleaning Air Heaters

Ljungström Units. Means should be provided for cleaning the surface of all air heaters as they are always subject to fouling from fly ash and dust in the flue gases.

With the Ljungström type of air heater, stationary steam soot blowers are usually located above and below the heating elements. Closely spaced nozzles sweep the heating elements as the rotor turns. To supplement this cleaning, a water-washing device using warm water is often provided for the air side. A hopper in the duct below the unit traps the waste water. This drain hopper is also shown in Fig. 1. During the washing period, it is necessary to reduce the rotor speed which is accomplished by means of a reducing gear. Air motors for slow-speed driving are being used with success, providing a minimum rotation of 1 revolution per 15 min.

Soot deposits materially increase the resistance to flow and the fan power consumption. However, the heat transfer is not necessarily materially affected, because of the regenerative principle, since the heat is not required to pass through the metal as is the case with plate and tubular units.

The Richmond Station air heaters are periodically water-washed. These 600,000-lb per hr boilers are not equipped with economizers, and outlet-gas temperatures from the air heaters are approximately 400 F at full load. At minimum boiler load, it is attempted to maintain 300 F or higher.

It has not been necessary to wash the air heaters on 600,000-lb per hr boilers at the Schuylkill Station. These latter units are equipped with economizers but outlet-gas temperatures from the heaters are higher than with the Richmond units. The higher gas temperature and the smaller quantity of fly ash through the heater because of ash trapped below the economizer probably accounts for the difference in operating practice.

Tubular Units. Cleaning the tubular air heater is usually more difficult. Water washing during periods of outage is most common. Some installations are successfully cleaned by means of high-pressure air lances alone.

Troubles Experienced

An analysis of troubles reported by one boiler manufacturer and experienced with various types of air heaters in utility and industrial service over a period of approximately 14 years indicates corrosion as the greatest offender. Such corrosion occurred with low unit gas temperatures and at the cold end. Recirculation methods either remedied this trouble or prolonged the life of the metals. In some cases, improved distribution of gases, installation of baffles, and tightening of the duct to prevent leakage improved performance of the equipment.

A discussion of troubles which have occurred should not overshadow the fact that in most cases they were rectified. Further, the troubles actually occurred in only a very small proportion of the total boiler installations.

Experience With Plate-Type Heaters at the Deepwater Station

During 1930, four plate-type sectional air heaters, five sections high by three sections wide, 90 plates per section, No. 14 gage sheet steel, containing 0.25 per cent Cu, 46,400 sq ft, were installed on pulverized-fuel-fired boilers. At maximum boiler load of 330,000 lb per hr evaporation, the gas temperature out of the unit is approximately 325 F.

Two plate-type sectional air heaters, five sections high by three sections wide, 102 plates per section, No. 14 gage sheet steel, containing 0.25 per cent Cu, 52,800 sq ft, were installed on reheat boilers. At maximum boiler load of 290,000 lb per hr evaporation, gas temperature out of the unit is approximately 325 F.

This station has operated at a very high load factor over the 11-year period, and no repairs nor replacements have been made on the air heaters. When the boilers are off at infrequent intervals, the air heaters are blown out with air and regular inspections are made for leakage.

However, during the first year the plant was operated, when burning a poor grade of coal, it was necessary to wash the air heaters frequently with high-pressure water, but this practice was not continued sufficiently long to cause any trouble. This experience applies to four standard and two reheat boilers installed in the plant.

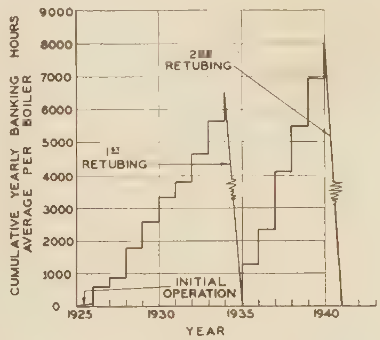

Fig. 2 Yearly Banking Hours, Showing Retubing of Air Heaters for Twelve Stoker-Fired Boilers at Richmond Station

Plate-Type Heaters at Chester Station

The paper[3] by N. E. Funk, previously referred to, included statistics for Nos. 5 and 6 plate-type heaters installed in the Chester Station. The life of these units was exceptionally short, 2 and 4 years, respectively. This short life is attributed to the inability to clean the plates properly, which resulted in excessive corrosion. Nonuniform gas flow, because of cleaning difficulties, probably accelerated the corrosion. These plate units were replaced with the tubular-design heater.

Tubular-Air-Heater Study

Richmond Station. Fig. 2 indicates the average life of tubes on twelve 200,000-lb per hr stoker-fired boilers at the Richmond Station. The original heater installation, 1925, consisted of hot-finished seamless-steel tubes, $2^1/_2$ in. outside diam, 25 ft $^1/_4$ in. long, No. 12 gage, having 22,072 sq ft of surface. During 1934 and 1935, after 10 years of operation, it was necessary to retube the air heaters because of excessive corrosion. Retubing was completed on the twelve units using electric-resistance and lap-welded No. 10 gage steel tubes. At the end of 1940, it was again necessary to retube the air heaters. The greatest number of defective tubes was at the back of the preheater, where the

tubes are first contacted by cold air. There was no apparent choice between the life of the electric-resistance and the lap-welded installations.

Boiler banking during the last 6 years was higher than during the previous 10-year period, as the chart, Fig. 2, indicates, so an investigation followed to determine if lower tube temperatures were maintained during the banking period, which might accelerate sulphur corrosion.

An analysis of recent conditions, Table 1, indicates that the coolest tubes in the air heater are warmer while the boiler is banked than during normal operation at higher rating. This is to be expected, since, during the banked period, the gases are entrapped and very small quantities of cold air are passed over the tubes. It is also possible that a distillation of the coal takes place, depositing moisture on the tubes, facilitating corrosion.

At low boiler ratings additional readings were taken. The gas temperatures are in the same range as during banking, but the tube temperatures have decreased, due to the introduction of cold air across the tubes. The short life of the tubes could not therefore be attributed directly to banking hours.

Chester Station. Table 2 gives a further case history of air heaters at the Chester Station over the life of the units. The corrosion conditions were in general similar to experience at the Richmond Station. Active corrosion occurred inside the gas tubes at the upper rear section where cold air sweeps the tubes. It will be noticed that boilers Nos. 2, 4, 6, and 8 have been relatively free from corrosion, as compared with Nos. 1, 3, 5, and 7 units. These latter units were affected to a greater extent because of their location in close proximity to a row of windows with an ambient temperature of 12 to 14 F below the opposite row. The higher gas-outlet temperature on No. 8 boiler, 400 F, compared to 300 F and below for the others, accounts for the satisfactory tube conditions with this unit.

These tubular units are designed so that the gases make one pass through the 25-ft-long tubes. The air makes four passes over the tubes from the fans to the boiler. Most severe corrosion extended to 6 in. below the second tube sheets with some corrosion showing below the third tube sheet. The remaining sections were relatively free from attack.

Conclusions on Corrosion

During periods of operation with low gas temperatures, particularly when gas temperatures are below approximately 300 F, severe corrosion may exist.

The tendency toward corrosion seems to be more severe with stoker-fired units than with pulverized-fuel-fired units.

On tubular air heaters, the corrosion exists inside the tube and is greatest in the vicinity where the incoming cold air passes over the hot tubes. The first bank of tubes struck by the cold air is most affected. Similarly, with the regenerative type of unit, most severe corrosion exists on the plates at the cold-air end.

The immediate cleaning of air heaters, when a boiler is taken off the line, may be an important factor in retarding corrosion.

Maintenance Costs of Air Heaters

An investigation of Fig. 2, showing the life of tubular air heaters at Richmond, and Table 2, indicating experience with various types of air heaters at the Chester Station, has provided information for additional comparisons. When it becomes necessary to replace tubes due to corrosion, usually the entire tube nest is

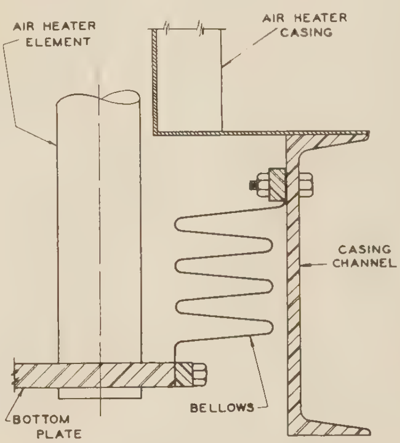

Fig. 3 Bellows-Type Expansion Joint

replaced. During the period, however, some new tubes may have been inserted and others blanked out of service. Replacement costs are negligible until the time for complete retubing, when an appreciable capital expenditure is required. During this period, leakage may be cumulative until retubing takes place, at which time with new tubes and tight tube sheets, it is again eliminated. An example of a method used by The Babcock & Wilcox Company to make a tight air-heater casing, particularly at the ends where the tube sheet has to move, is shown in Fig. 3. This construction employs a bellows-type expansion joint between the bottom plate and the casing channel.

With the Ljungström air heater, leakage is necessarily present, due to the rotating element and the method of sealing. Expressed in percentage of gas entering the unit, it ranges from 6 to 8 per cent at full load, increasing with decreasing boiler loads and wear. With proper maintenance of seals, this leakage should be held within normal limits. Variations in differential pressures will necessarily affect this leakage.

years 1926 to 1940, inclusive, are given in Table 3. The tabulation shows the number of Ljungström air heaters in operation by December 31, of the respective years indicated, average size of heater, replacement value of heating surface and of spare parts, expressed in percentage of heater cost f.o.b. Wellsville, N. Y. Cost of parts includes rebuilding of old units to rotor center support and center drive, but does not include replacement cost of fan parts where integral forced and induced fans are used.

Oil-Refinery Practice

A refiner reports that the main advantage to an oil refinery of using air heaters is that, in many cases on oil-cracking stills, the inlet oil temperature is in the neighborhood of 700 F, with the exit gas temperatures in the range of 950 F, when convection banks are used. When the inlet oil temperatures are around 700 F, it is necessary to install some heat-recovery equipment. A recent paper[5] by O. F. Campbell and T. B. Kimball presents further information relative to refinery practice. Among other items, they consider the economy of eliminating the convection bank of a cracking-still furnace and substituting an air heater.

Additional advantages when using an air heater lie in the fact that there are fewer oil tubes to clean, that there is less original cost of alloy tubes and headers, and that preheated-air temperature increases the rate of heat transfer by radiation, due to the higher furnace temperature.

An analysis of Ljungström air heaters of various sizes and varying quantities of flue gas and air handled reflects average high-temperature air-heater operation for oil-refinery practice as follows:

Flue-gas inlet temperatures to the air heaters range between 910 and 1275 F. Gas outlet temperatures range between 315 and 650 F. Air outlet temperatures from the air heater are similarly higher than experienced in public-utility practice and range from 700 to 1055 F.

One refiner, using the tubular-type air heater, reports this experience with refinery equipment during the last 10 years:

A tabulation of expected performance and test data on tubular-type air heaters indicates that the actual performance is closely in line with that specified and that these refinery air heaters also operate at rather high temperatures when compared to utility-boiler practice. These higher temperatures are accounted for through the use of heat exchangers providing feed temperatures above 500 F. With cracking stills and furnaces, a "soaking" section is usually included in the convection path of the furnace where the oil must be held at temperatures in the vicinity of 1000 F. The primary purpose of these refinery air heaters, therefore, is to reduce what would otherwise be excessive stack loss.

In marine installations, this same company finds it preferable to use sufficient stage heaters to give satisfactory boiler-feed temperatures without the use of economizers and to obtain a proper stack temperature and boiler efficiency by the use of an air heater. In this way, maintenance difficulties with economizers are eliminated and a higher air temperature is obtained which is of considerable advantage when using a very heavy low-grade fuel oil.

In refinery practice, generally higher temperatures account for the absence of corrosion difficulties.

Recent Applications of Air Heaters

An analysis of the last 2 years' sales of the regenerative air heater, applied to boilers for public-utility service, indicates a gradual increase in size of unit (square feet of heating surface)

and in heat recovery. Twenty of the boilers considered are rated 500,000 lb per hr or above, Table 4.

The efficiencies for the various installations 500,000 lb per hr and above are tabulated and range from 46.8 to 64.2 per cent. This efficiency is by definition $\frac{T\text{ gas in} - T\text{ gas out}}{T\text{ gas in} - T\text{ air in}}$ for the regenerative unit. The per cent efficiency of the air heater, compared with the square feet of air-heater surface per boiler, indicates the trend in increased size and recovery. The limiting factor for percentage of heat recovery appears to be the acceptable minimum gas temperature and maximum air temperature.

Table 4 gives further details regarding the resistance through the units, the air temperatures, and the gas temperatures for the twenty representative installations.

An analysis of recent sales of tubular-type air heaters indicates a somewhat similar trend. Again, twenty of the most recent sales are tabulated as installed on boilers rated 300,000 lb per hr and above, where the limiting factors are indicated as the minimum gas temperature and maximum air temperature, Table 5.

Trends in Air-Heater Selection—Explanation of Charts

Fig. 4 presents graphically data pertaining to air-heater installations for public-utility service, obtained from boiler statistics compiled for the A.E.I.C. in a report of the Committee on Power Generation, for a 5-year period to date. Table 6 shows the actual tabulation. Only boilers installed, having a capacity of 100,000 lb per hr or over, are included. These boiler data show a predominance of pulverized-coal, oil, or gas fuel installations during the last 5 years with practically an equal division between the tubular and the Ljungström air heater. Relatively insignificant in number were those installations having a plate or steam air heater or no air heater.

Figs. 5, 6, and 7 further subdivide the installations among three boiler-capacity ranges, i.e., 100,000 lb per hr to 295,000 lb per hr, 300,000 lb per hr to 495,000 lb per hr, and 500,000 lb per hr and higher. Table 7 itemizes this subdivision.

With the lower-capacity boilers, the tubular air heater predominates. With the intermediate-sized boilers, the Ljungström shows a marked increase in popularity; there is a corresponding decrease in the use of tubular units. An analysis of

[5] "Regenerative-Type Air Heaters for Refinery Use," by O. F. Campbell and T. B. Kimball, A.P.I. Meeting, Tulsa, Okla., May 19–22, 1941.

NOTE: Only boilers 100,000 lb per hr or above included.

large-size boilers indicates all to be of the pulverized-coal, oil, or gas type with the Ljungström heaters greatly predominating in this class of service.

Summarizing all the charts, we find a general trend toward the application of the Ljungström units with an increase in capacity of the steam generator. This is particularly noticeable during the period of increase in capacity in existing power-plant structures. During the latter part of the period, when entirely new plants and structures were being erected, this tendency was not so pronounced; perhaps due to greater space available in the new plant for the generally larger tubular-type air heater.

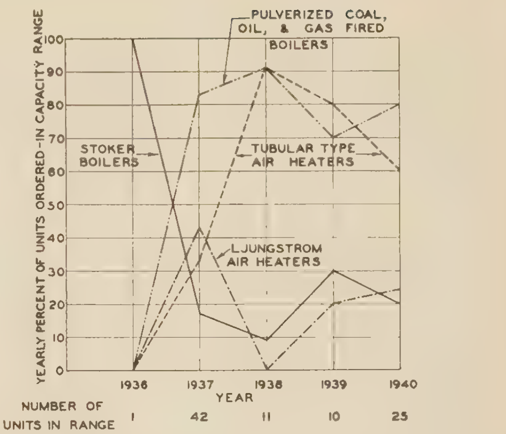

FIG. 5 TYPES OF AIR HEATERS INSTALLED IN BOILERS WITHIN THE CAPACITY RANGE OF 100,000 LB PER HR TO 295,000 LB PER HR

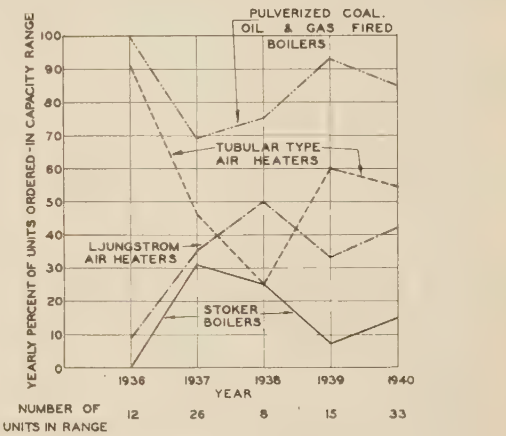

FIG. 6 TYPES OF AIR HEATERS INSTALLED IN BOILERS WITHIN THE CAPACITY RANGE OF 300,000 LB PER HR TO 495,000 LB PER HR

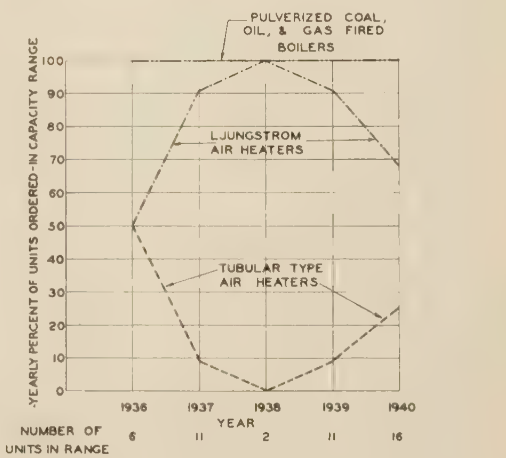

FIG. 7 TYPES OF AIR HEATERS INSTALLED IN BOILERS WITHIN THE CAPACITY RANGE OF 500,000 LB PER HR TO 1,000,000 LB PER HR

In conclusion, the authors wish to thank the various manufacturers and the users of air-heater equipment for their assistance in supplying information incorporated in this paper.

Discussion

O. F. Campbell.[6] The authors are to be complimented for their efforts in assembling pertinent air-heater data for 1926–1941. From the data included in the paper, it would appear that a purchaser of air heaters may make a more intelligent choice of a preheater for definite duty.

The corrosion of air heaters, which is apparently quite indefinite, occurs in many instances when the exit flue gases are well above the dew point. Several cases of air-heater corrosion have been attributed to condensation of acid after the flue gases have left the air heater, where the duct construction has been such as to allow the condensed acid to drip back on the air-heater elements or run down the sides of the exit flue-gas duct into the air heater. The cases referred to occurred where the installation of the air heater was placed outdoors, without insulation of the exit flue-gas duct or other protection. It is suggested that any air-heater installation made outdoors should be so designed as to guard against condensed acid falling or dripping back on the air-heater elements.

Each type of preheater has its own advantages and disadvantages. One of the advantages of the regenerative-type air heater is its apparent ability to stand abuse. An illustration of the severe duty imposed upon a Ljungström regenerative air heater is cited. The air heater was installed on a cracking still. The forced- and induced-draft fans were driven with an electric motor, and a power interruption occurred. Immediately after the power interruption, the soot and sulphur deposits on the air-heater elements ignited and two sections of the rotor were fused together or melted. Upon resumption of power, it was found that the rotor could not be turned with the ordinary driving mechanism. The rotor was then started manually by the application of a 48-in. pipe wrench to the pinion-gear shaft. After the rotor was loosened, the ordinary driving mechanism had sufficient power to turn it over. The still then continued to operate for approximately 50 days after the power interruption. Combustion conditions were not satisfactory because of the two sectors of the rotor which were destroyed but, nevertheless, the still continued in operation.

Where electrical energy is the sole source of power for the forced- and induced-draft fans, and power interruptions are likely to occur, smothering steam should be used at the entrance of the air heater in sufficient quantity to prevent burning of deposits on the air-heater elements and consequent destruction of the air-heater rotor. For refinery practice, smothering steam should be used on all air-heater installations to protect the air heater when power failure occurs.

J. H. Sengstaken.[7] The authors have given us a complete and extremely interesting report on air preheaters and their development since the paper[3] by N. E. Funk in 1926. This discussion will attempt to indicate how a number of operators, whose boilers have been designed for high over-all efficiency and low exit-gas temperatures at normal loads, have overcome the possibility of clogging and corrosion at low loads when the heating surface in the preheaters normally might be expected to reach the dew point of the gases.

With particular reference to the Ljungström air preheater, which operates on the regenerative cycle, the metal temperature is not affected by any deposit of soot on the heating surface at the cold end. Moreover, all of the surface passes through all of the gases and air so that all of the heating surface at any point along the path of gas travel is at the same average temperature.

These units are designed so that under normal conditions the rates of gas and air flows are very nearly equal. Thus, the average metal temperature at the cold end, during one revolution of the rotor, is an arithmetic average of the exit-gas and entering-air temperatures. During the course of one revolution of the rotor, the heating-surface temperature at the cold end will vary between 10 and 20 deg above and below the average temperature for that revolution. Thus, if the temperature of the air entering the preheater is added to that of the gases leaving, and a certain amount deducted for the variation in the cold-end metal temperature during a revolution, a totalized figure will be obtained which will indicate the actual minimum temperature of the heating surface. This can be maintained above the dew point by the use of air by-pass or air-recirculating ducts. The control can be either manual or made entirely automatic by the use of damper-operating equipment, actuated from the totalized temperature. In every case where this method of operation has been established, difficulties from clogging and corrosion have been entirely eliminated.

As to recirculation, the higher mass velocity of the air passing through the preheater tends to pull the metal temperature down toward that of the incoming air. The contrary is true with by-passing, since the mass velocity of the air is reduced and the heating surface then tends to rise toward the temperature of the gases. This is a safety factor in favor of air by-passing.

In a number of cases, the writer has discovered that, while apparently the temperature of the metal at the cold end, as indicated by the recording instruments measuring exit-gas temperature and room-air temperature should be safely above the dew point, clogging has occurred on perhaps one air preheater in a row. Investigation indicated that such a preheater was near an open window with the forced-draft fan taking air directly from outside. Thermocouples placed in the air inlet to the preheater have indicated this immediately. The control herein described can overcome difficulty from this source automatically.

Other examples of corrosion which have occurred, when apparently the temperatures were correct, have been solved by cleaning the preheater immediately after the boiler has been shut down and before the preheater has had an opportunity to cool off. It has been found that severe corrosion can sometimes take place during the shutdown period if the preheater has not been cleaned. Certain types of deposits on the surface absorb moisture from the cool air drifting through the preheater, resulting in severe corrosion. Cleaning the surfaces has taken off the deposits thereby entirely eliminating the corrosion.

Authors' Closure

The authors wish to express their thanks to those who offered discussion on this paper and, further, their appreciation of the interest shown by those who submitted material incorporated in the paper.

More recent experience obtained by the authors' company would indicate that the by-pass method for the reduction of corrosion is most satisfactory. The recirculation method, which was installed at Chester Station, whereby a portion of hot air was discharged from the air heater and returned to the forced-draft fan, did not prove practicable. With this arrangement there was a tendency for fly ash in small quantities to be carried through to the forced-draft ducts and to be discharged in the air near the forced-draft-fan inlet.

The heated air discharged in the vicinity of the forced-draft-fan floor was also an objectionable feature as the recirculating duct was opened directly before the forced-draft-fan inlets.

The system at Chester was adjusted to provide for a direct air by-pass.

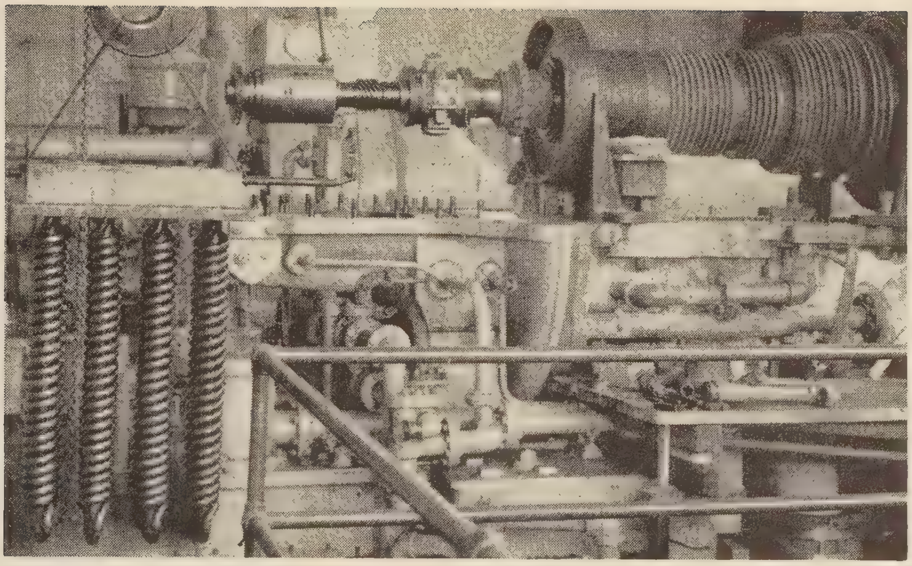

FIG. 1 OIL COOLER, SHOWN AT LEFT, REMOVED FROM A 5000-KW TURBINE FOR INSPECTION
(Inhibited turbine oil was installed in May, 1930; the cooler was removed for inspection in May, 1940, after 10 years of service without cleaning.)

Stability Characteristics of Turbine Oils

BY HOWARD R. PETERSON,[1] CHICAGO, ILL.

This paper reviews the phenomena of turbine oil oxidation, its effects on turbine lubrication, and the use of inhibitors. Service data on an inhibited turbine oil, free from asphaltene-forming constituents, manufactured by the author's company and used in 560 turbines, are presented. These data show a retention of essential properties after 14 years of service. The problem of turbine corrosion is briefly dealt with, responsibility for its prevention being placed upon designers and operators as well as upon oil refiners.

THE need for uninterrupted operation of turbines and turbogenerators, particularly during a period of emergency and rapidly increasing power demand, has led to an intensification of the study of lubricants and their influence on performance. The selection of an oil to meet the relatively broad specifications of most turbine designers, and provide satisfactory lubrication when new, is not a difficult task. The principal problem is one of selecting an oil which will retain its essential characteristics under service conditions. Turbine outage attributable to lubrication is largely caused by deposits resulting from chemical changes in the oil.

Petroleum oils are extremely complex mixtures of hydrocarbons of a variety of molecular sizes and types, varying from paraffinic to aromatic in structure. Various constituents differ in their resistance to oxygen absorption, some being very stable. Turbine oils, generally low in viscosity, are somewhat less resistant to oxidation than heavier oils.

The products of oxidation are of numerous types, depending upon the particular combination of oxygen with the hydrocarbons. Peroxides, alcohols, aldehydes, ketones, lactones, asphaltenes, and organic acids of various molecular weights, volatility, and corrosiveness are among the possible resultant products. Some of these, such as the asphaltenes, tend to precipitate as sludge, while both acids and asphaltenes serve as emulsifying agents in the presence of moisture. The acids may attack metal surfaces, forming metal soaps which not only are emulsifiers but, being relatively insoluble in oil at low temperatures, deposit in lines, coolers, and couplings. Other oxidation products may interfere with the operation of oil-actuated governors. Viscosity changes, sludging, emulsions, and acidity are fundamentally oxidation problems.

The complicated nature of the reactions to which oils are subject is shown by Dornte, Ferguson, and Haskins (1, 2, 3),[2] who describe three types of oils, viz.:

1 Those which oxidize autocatalytically, i.e., whose rate of oxidation is increased by the reaction products.

2 Those whose rate of oxidation is unaffected by nonvolatile reaction products.

3 Those whose rate of oxidation continuously decreases due to decreasing concentration of reacting compounds.

CONDITIONS FAVORABLE TO OXIDATION

The conditions to which turbine oils are exposed are favorable to oxidation. Rapid circulation in the presence of air, contact with various metals, of which some are active catalysts, and ex-

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

posure to elevated temperatures are among the unfavorable influences. Other conditions being constant, the rate of oxygen sorption is an exponential function of temperature, doubling or each increase of 12 to 18 F. Careful control of temperature is therefore of prime importance.

Investigators who have studied the effects of various metals on the oxidation rate of turbine oils are in general agreement that copper is the most active, followed by brass, tin, and zinc. Iron, nickel, and aluminum have much less effect, although iron oxides may serve to promote oxidation. Staeger (4) also found that the area of immersed metal has an influence, but not a proportional one. These conclusions should be of value both in turbine design and in laboratory investigations of oxidation phenomena.

Accelerated Oxidation Tests

For purposes of investigation, accelerated oxidation tests are desirable. The literature describes a large number of tests, with temperatures varying from 212 to 392 F, and test periods from 5 to 500 hr. Some tests use oxygen and others air and water, or various metal catalysts may or may not be used. The Rogers stability test (5) has been largely employed by the author's company, since it was established that this test substantially duplicates oil behavior in a dry turbine. Later tests, such as the modified Farmer test, and the test now under consideration by the A.S.T.M. Turbine Oil Committee, impose more severe conditions. It is hoped that this investigation will lead to a generally accepted procedure. Accelerated oxidation tests are at best difficult to interpret. Conditions of service must be simulated or results will be misleading. Actual service data will continue to play the most important role in the evaluation of turbine oils.

Advance in refining technique has resulted in a marked improvement in the stability of turbine oils. Through acid treating and solvent extraction, unstable types of molecules may be removed while preserving the more stable ones. Insufficiently refined oils are subject to excessive deposit formation, whereas some highly refined oils are susceptible to rapid acidity development, presumably due to the removal of natural oxidation inhibitors. This hypothesis led to the use of added inhibitors which, in low concentrations, serve effectively to retard the absorption of oxygen by the petroleum hydrocarbons.

Addition of Inhibitors to Turbine Oils

Inhibitor response of turbine oils is affected by the degree of refining. Since highly treated oils are more uniform in chemical composition, the oxidation reactions to which they are subject are more limited and, hence, easier to control. The selection of a satisfactory inhibitor, however, is by no means a simple task and must be based upon a broad background of experience both with the oil and the inhibitor. Acidity development may be retarded by adding inhibitors to oils insufficiently refined to remove asphaltene-forming constituents completely. This may result in the formation of turbine deposits without a corresponding increase in acidity of the oil.

Patents issued on application filed by Rogers in 1926 (6) cover the addition of certain inhibitors to highly refined white viscous oils from which asphaltic constituents had been removed. Oxidation tests of turbine oils embodying this invention resulted in the conclusion that, under normal operating conditions, they might be expected to last indefinitely. This conclusion was confirmed by experience in a limited number of turbines prior to 1927, at which time an inhibited turbine oil was placed on the market. In 1931, Fitzgerald (7) reported an average acidity of 0.04 mg/KOH/gm on the inhibited oil in sixteen turbines after from 4 to 21 months of service.

Service Experience With Inhibited Turbine Oil

Fig. 2 shows the number of turbines in which this oil has been in service, as of December 31, for each year. Of the 560 turbines shown, 69 are of 10,000 kw capacity or over, and 32 are of 25,000 kw or more. Since it has been a practice to obtain samples from each turbine at regular 6-month intervals, there is now available

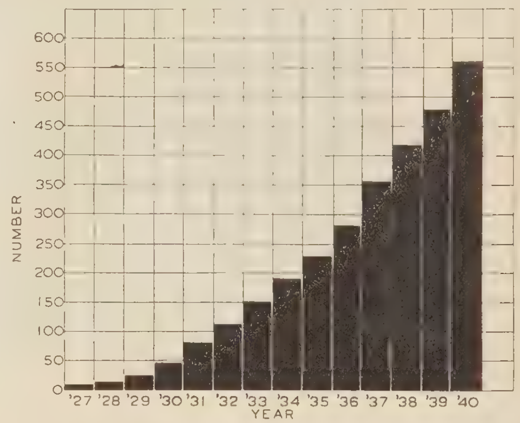

Fig. 2 Number of Turbines Operating on Inhibited Turbine Oil

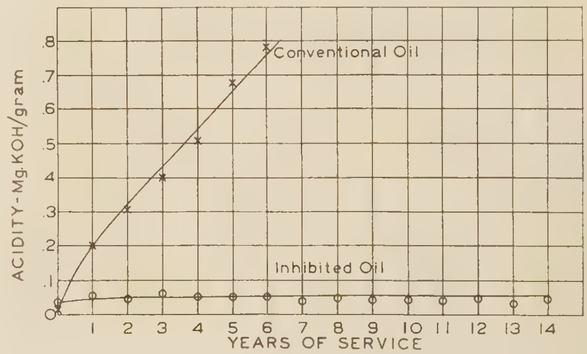

Fig. 3 Comparison of Acidity Development; Conventional Versus Inhibited Turbine Oil

a unique background of performance data which, in view of the increasing attention being given to inhibited oils, may prove of interest.

Two grades of this type of oil are in use, a medium grade of 155 to 160 sec viscosity for direct-connected turbogenerators, and a heavy grade of 310 to 320 sec for geared units. Under severe oxidizing conditions, the viscosity increase of conventional oils has frequently been troublesome. Inspections of samples from those units in which the inhibited oil has been in use for 9 years or more show a viscosity increase of 3 to 7 sec, the average viscosities being 159 and 319 sec for the medium and heavy grades, respectively.

Fig. 3 shows a comparison of acidity development between a conventional oil and the inhibited oil. Since asphaltic constituents have been entirely removed from the inhibited oil, acidity is an adequate criterion of its oxidation. Data on the conventional oil were secured from records of inspections of all samples of medium-grade oils from direct-connected turbogenerators examined during the last 3 years, for which length of service was known. Insufficient data were available to extend this over more than 6 years, since in a majority of cases the oil

is changed before expiration of that period. Data on the inhibited oil were secured from records of periodic sample inspections from 560 units.

In 1933, on the basis of experience with about 100 installations, it was found possible to guarantee that the neutralization number would not exceed 0.15 mg/KOH/gm during the life of the turbine, if the system is thoroughly cleaned prior to installation, and if the temperature of oil from the bearings does not exceed 170 F.

Steam Emulsion Values of Various Oils

Fig. 4 shows the A.S.T.M. steam emulsion values on conventional and inhibited oils of medium grade at the end of various periods of use. Data on conventional oil were secured by inspection of all samples of medium grade secured over a period of 6 months for which length of service was known. The results are not unexpected in that an initial rapid decrease in demulsibility is followed by a slower gradual decrease. Inasmuch as steam emulsion values are regularly determined on only about 25 per cent of all routine samples of the inhibited oil, it was necessary to supplement the available data by examination of not less than five samples, representing each of the various periods of service. All were of medium grade.

While the initial steam emulsion value of the inhibited oil is

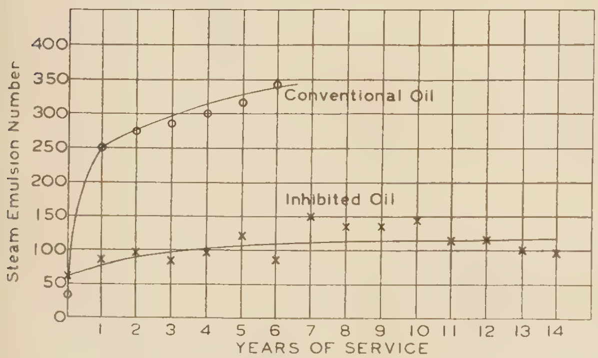

Fig. 4 Comparison of Demulsibility; Conventional Versus Inhibited Turbine Oil

somewhat higher than for a well-refined conventional oil, the decrease in demulsibility is comparatively slight, even after 10 to 14 years of service. This illustrates the inadvisability of establishing extremely restrictive demulsibility specifications on new oil.

It must be recognized that steam emulsion values are seriously affected by the presence of contaminants. Troublesome emulsions may occasionally result even with oils of excellent demulsibility and low acidity. Although such an emulsion may be termed "sludge" by operators, analysis reveals a significant distinction. A typical emulsion, involving a conventional oil, consists of the following:

	Per cent
Petroleum oil	41.7 (acidity 0.6)
Water	57.0
Naphtha insoluble	1.3
Chloroform soluble	0.9
Ash (iron oxide)	0.2

It is apparent from the high acidity and chloroform soluble that extensive oxidation of the oil has occurred. It is reasonable to assume that this emulsion was caused by oil oxidation.

In one case a very persistent emulsion, involving the inhibited oil, was found upon analysis to consist of the following:

	Per cent
Petroleum oil	34.0 (acidity 0.08)
Water	65.0
Naphtha insoluble	0.9
Chloroform soluble	0.01
Ash (iron oxide and silica)	0.9

In this case the low acidity and chloroform soluble show that oxidation is not extensive and that the emulsion was not caused by products of oxidation. The high ash indicates the presence of contaminants remaining in the oil as a result of not having equipment for their removal, and that the contaminants are responsible for the emulsion. In a similar case the emulsifier was found to be a product resulting from the oxidation of cereal dust which found ingress into the lubrication system.

Of the 560 turbines under discussion, about 60 per cent are provided with either filters or centrifuges, while the remaining 40 per cent are not. Even in the case of oils of high oxidation stability, adequate purification devices have a very important function in the removal of water, foreign contaminants, and iron oxide, and the prevention of their attendant ill effects on oil quality.

Turbine Corrosion Problem

During the last two or three years, considerable attention has been focused on the problem of turbine corrosion (8), especially in connection with marine turbines and gear sets. If severe, this may result in impairment of governor operation, particularly in governors of recent design having close tolerances. The problem is further aggravated by operation under constant load, resulting in a reduced flow of oil through the governor. Another unfavorable result of rusting is the fact that iron oxide in finely divided form may serve as an emulsifier and as an oxidation catalyst.

The admixture of small amounts of used oil having moderately high acidity with unused oil is undoubtedly effective in retarding corrosion and has been advocated by some for use in new turbines. It should be kept in mind, however, that this procedure will materially reduce the demulsibility of the new oil. The addition of even small amounts of highly oxidized oil may also greatly increase the oxidation rate of the new oil, as well as result in the precipitation of sludge. Unless specifically compounded to prevent corrosion, however, highly refined oils may be deficient in this property. Since 1927, the inhibited turbine oil described has been compounded to include an antirusting agent in order to provide the necessary degree of rust prevention.

Corrosion prevention is necessarily relative. Under certain conditions of temperature and humidity encountered in turbine operation, the most effective specially prepared rust preventives will give protection for only a short period. It will probably not be feasible to treat turbine oils to such an extent that protection will be provided under all conditions of service, although a reasonable degree is entirely proper. This should not be accomplished, however, at the expense of such desirable qualities as low acidity, good demulsibility, and high stability.

Accelerated tests for rusting tendency, such as the modified Kuebler test (8), will undoubtedly prove to be of assistance in the evaluation of oils. Minimum standards can be established, however, only after much correlation between laboratory results and service data.

Turbine design, metallurgy, improved protective coatings, and maintenance practices must share with turbine oil the responsibility for the correction of this problem, just as each has contributed toward the present high standard of performance.

The Steam-Turbine Regenerative Cycle—An Analytical Approach

By J. Kenneth Salisbury,[1] Schenectady, N. Y.

The author has found that with other conditions fixed the heat rate of a turbine depends only upon the fractional quantity of steam extracted, regardless of internal variations in the heater cycle. A method is presented in this paper for determining quickly and accurately the improvement in heat rate resulting from regenerative feedwater heating with any steam conditions. The results are shown in Fig. 1, which is useful in estimating heat rates and in settling the design of a feedwater-heating system before final design figures are completed.

Nomenclature

The following nomenclature is used in the paper:

- a = coefficient of x^2 in quadratic approximation
- b = coefficient of x in quadratic approximation
- c = subscript denoting state-line end point without exhaust loss (c denotes "condenser end")
- e = subscript referring to bleeding operation
- h = enthalpy of feedwater (saturated liquid)
- n = number of heaters
- p = $[(H - h) - t]$ at mid-rise
- r = heat rate, Btu per Btu (conversion constant 3412.75 omitted)
- s = subscript denoting throttle or saturation conditions; also
- s = $[(H_s - h_s) - t]$ (at throttle)
- t = $(H - h)$ at state-line end point, i.e. $(H_c - h_c)$
- w = pounds total extraction per pound condenser flow
- w_x = pounds extraction below any given extraction point per pound condenser flow
- x = fraction of rise in liquid enthalpy between hot well and throttle = $\dfrac{h - h_c}{h_s - h_c}$
- A = area used as a parameter (= $^1/_3\, a + {^1/_2}\, b$)
- C = condenser flow
- C_a = coefficient of ax^2 term = $f(n, R/t)$
- C_b = coefficient of bx term = $f(n, R/t)$
- E = extraction quantity
- A.E. = available energy
- E.L. = exhaust loss, Btu per pound of condenser flow. (Subscript N indicates nonextraction; e indicates extraction)
- F_1 = factor defined as ratio of extraction exhaust loss in Btu to nonextraction exhaust loss in Btu
- G = per cent reduction in nonextraction heat rate with infinite number of heaters
- H = enthalpy of steam from state line
- N = subscript referring to nonbleeding operation
- η = internal efficiency of turbine, from throttle to exhaust, including all losses except exhaust loss and mechanical losses
- P = per cent of G obtainable with a finite number of heaters
- P_p = per cent of G obtainable with a finite number of heaters at the optimum feedwater temperature
- R = rise in liquid enthalpy above hot well (= xR_s)
- U = turbine used energy without exhaust loss
- V = turbine used energy per pound throttle flow when extracting for feedwater heating

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Introduction

The origin of the philosophy that reductions in the nonextraction heat rate depend upon a few relatively simple parameters is lost in antiquity. These parameters will be defined herein, together with a method for their use. We will also demonstrate in this paper the use of this philosophy in calculating many useful functions which occur frequently in heat-balance work.

In determining turbine performance, the nonextraction heat rate is always known or easily obtainable by the turbine designer and by the purchaser, from the nonextraction water rates. The nonextraction turbine heat rate is defined as the heat supplied in the boiler to the working fluid per kilowatthour generated at the generator terminals, when operating without regeneration. The "quadratic-approximation" method (Q.A. method) permits rapid calculation of the bleeding performance, with accuracy, from the nonbleeding heat rates.

Methods will be demonstrated whereby it is possible to calculate or find from curves:

1 The total quantity of extraction with an infinite number of heaters, heating to the saturation temperature corresponding to throttle pressure, for any turbine efficiency, or steam conditions.

2 The reduction in nonextraction heat rate, resulting from the use of such a hypothetical cycle.

3 The total extraction quantity with any finite number of heaters, heating to any feedwater temperature.

4 The reduction in nonextraction heat rate obtained with any finite number of heaters, heating to any feedwater temperature.

5 The variation in this reduction with variation in the number of heaters.

6 The variation in this reduction with variation in feedwater temperature.

7 The optimum feedwater temperature for any steam conditions.

8 A comparison of regenerative power-plant cycles, using only theoretical water-rate tables to supplement the curves given herein, or, alternatively, using the table of nonextraction heat rates (Table 2).

9 A method of dealing with all of these variables mathematically.

The desirability of such methods is unquestioned. It is highly desirable, for example, in the preliminary design of a power plant to be able to state definitely the number of feedwater heaters which is compatible with the economics of the particular installation. Invariably there is some question as to the steam conditions which should be chosen for a given power plant. It will be seen that the evaluation of various steam conditions depends to some extent upon the feedwater-heating cycle to be employed. There is always the early necessity of specifying a

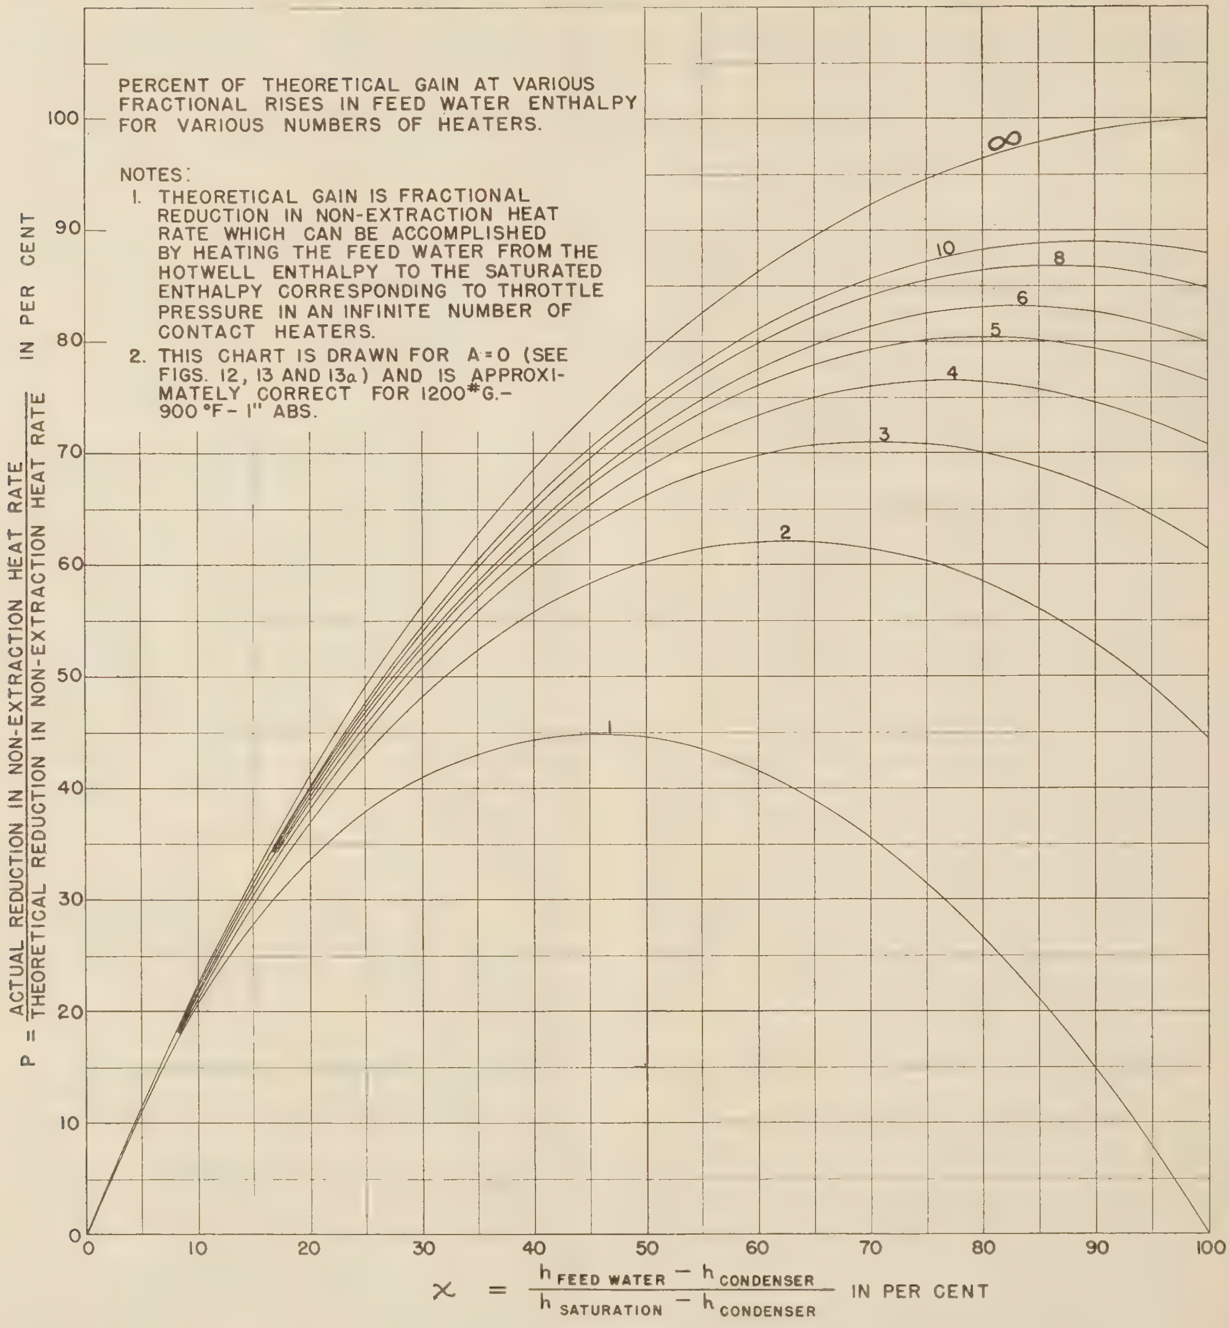

Fig. 1 Curves Correlating Fraction of "Theoretical" Gain Against Percentage of "Possible" Rise for Various Numbers of Heaters

condenser, in order that quotations may be obtained from manufacturers at an early date to aid in making preliminary arrangement drawings of the power plant. From the standpoint of the turbine designer, it is extremely vital that the duty of the exhaust end of the turbine be known in order that he may properly proportion it to handle the flows. The boiler manufacturer invariably is interested in the feedwater temperature in order that he may design his heating surface in both the economizer and the boiler. Use of the curves and of the methods presented herein will not only make possible rapid solutions of all these questions, but will also suggest many other uses of the basic Q.A. method.

Let the reader be assured that, although in some cases it has been necessary to resort to mathematical formulations far beyond the author's original intention, it is by no means necessary that the user concern himself with the derivations and theory in order to reap a full measure of benefit from the results. Only simple arithmetic is required.

Ideally, the most economical way to operate a power plant is to pass the condensate from the condenser hot well through an infinite number of infinitesimal heaters, each of which is supplied

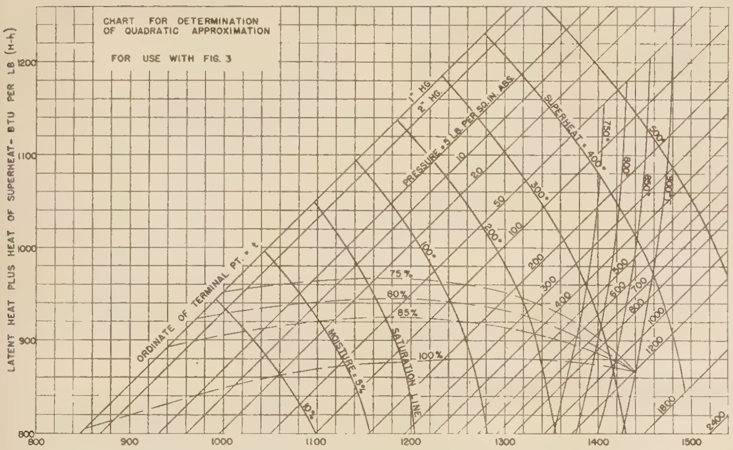

FIG. 2 CHART ILLUSTRATING VARIATION OF $(H - h)$ WITH STATE-LINE ENTHALPY FOR VARIOUS EFFICIENCIES

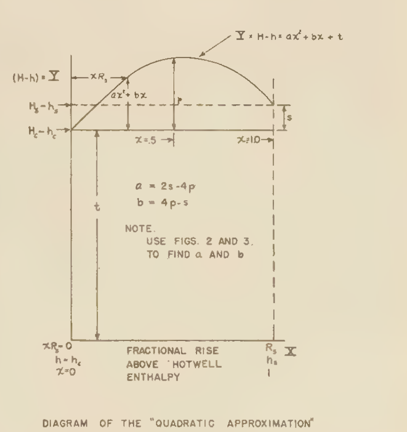

FIG. 4 DIAGRAM ILLUSTRATING METHOD OF OBTAINING QUADRATIC APPROXIMATION AND SHOWING NOMENCLATURE USED

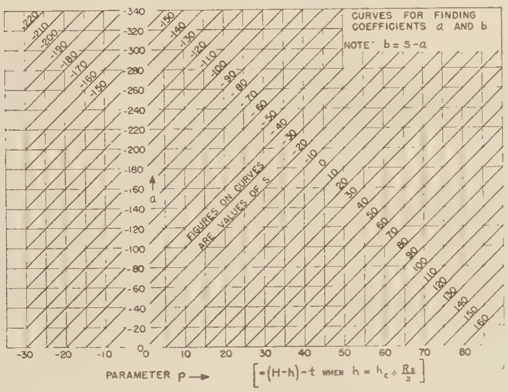

FIG. 3 CHART FOR DETERMINING COEFFICIENTS a AND b IN QUADRATIC APPROXIMATION $(H - h) = ax^2 + bx + t$

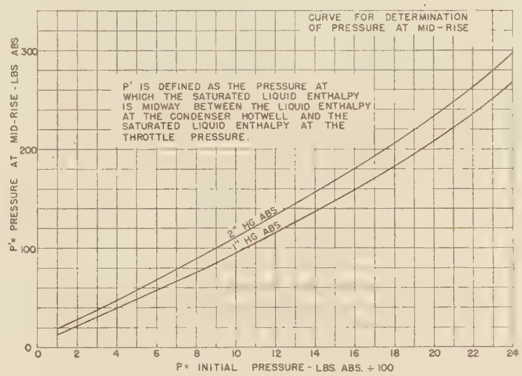

FIG. 5 CURVES FOR DETERMINING PRESSURE P' AT MID-RISE

by one of an infinite number of extractions in the turbine. In such a cycle, the heating of the feedwater most nearly approaches thermodynamically perfect reversibility, and the maximum "gain," or reduction in nonextraction heat rate, is obtained. Obviously, however, it is necessary to use a finite number of heaters; the smaller the number, the greater the degree of irreversibility and the greater the loss. With a finite number of heaters, the maximum gain is always obtained when the feedwater is heated to less than the saturation enthalpy corresponding to throttle pressure.

When the gains which result from heating in an *infinite* number of heaters to the saturated liquid enthalpy (corresponding to the throttle pressure) are known for various steam conditions, then it is possible to correlate the gains with *finite* numbers of heaters by plotting these gains as fractions of the "theoretical gain" against "fractional rise" for various numbers of heaters. The result of such correlation is shown in Fig. 1. The gains resulting from use of an infinite number of heaters could be obtained by numerical integration, using a large number of steps, but such a process is unsatisfactory, tedious, and subject to inaccuracies. Mathematical integration would be much more satisfying.

The regenerative feedwater-heating cycle has not heretofore been considered amenable to mathematical analysis. A method will be demonstrated by which turbine state lines[2] can be accurately described algebraically, using a "quadratic approximation." Further uses of the quadratic approximation suggest themselves as one becomes better acquainted with it.

PART 1

"Quadratic Approximation"

It has been observed that the heat available per pound of steam extracted for heating the feedwater is relatively constant throughout the whole state line. Using the method actually employed by turbine designers in drawing state lines, a curve of $(H - h)$ may be plotted against the fractional rise above the hot-well enthalpy which can be accurately approximated by the quadratic[3]

$$(H - h) = ax^2 + bx + t \qquad [1]$$

From analytic geometry, the coefficients a and b may be determined by the value of $(H - h)$ at any two points on the state line. We have chosen for convenience and accuracy two easily defined points, i.e., mid-rise and throttle conditions, respectively. The constant t must be determined from a third point which we have chosen to be the state-line "end point." (The liquid enthalpy at mid-rise is defined as that enthalpy which is midway between the liquid enthalpy at the condenser hot well and the saturated liquid enthalpy, corresponding to the throttle pressure. The state-line end point is the lower terminus of the state line,

[2] A turbine state line is the locus of the state points of the steam in the various stages of the turbine, with constant throttle flow.

[3] Originally a quartic was used, and then a cubic, but the additional accuracy did not justify the complication introduced.

with no exhaust loss.) By using Figs. 2 and 3, the constants a and b may be readily determined. The accuracy of the quadratic approximation is found to be well within allowable limits.

Checks were made to determine the amount by which this approximation varies from the actual state line as it would normally be drawn. In most cases the maximum discrepancy is less than 0.5 Btu and in a few cases, such as at 2400 lb initial pressure, it reached a maximum value of about 2 Btu. By the derivation, there is an exact check at the turbine exhaust, at mid-rise, and at the throttle. Intermediate points are of slight significance because, normally, the turbine manufacturer does not know the efficiencies of the various parts of the turbine as well as he knows the over-all turbine efficiency, and no attempt is made to predict the exact enthalpies at the various stages.

Fig. 4 indicates the manner in which the Q.A. is determined. Fig. 5 is presented in order that the pressure corresponding to mid-rise may be easily determined.

PART 2

Gain With Perfectly Regenerative Feedwater Heating Using an Infinite Number of Heaters

Since we are now able mathematically to handle extraction data, an expression for the reduction in nonextraction heat rate due to feedwater heating may be easily deduced.

By definition, the heat rate of the turbine cycle is the heat supplied to the working fluid per unit of output, that is

$$r = \frac{\text{Heat supplied}^4}{\text{Output}} \quad \ldots\ldots\ldots [2]$$

$$= 1 + \frac{\text{Heat rejected}}{\text{Heat supplied} - \text{heat rejected}} \quad \ldots\ldots\ldots [3]$$

For a *nonregenerative* cycle the heat rejected is

$$\text{Heat rejected} = 1 \cdot (H_c - h_c) \text{ (per lb condenser flow)} \ldots [4]$$

and the heat supplied minus the heat rejected is

$$(\text{Heat supplied} - \text{heat rejected}) = (H_s - H_c) = \text{Used energy} = U \ldots [5]$$

The heat rate, then, for a nonregenerative cycle is

$$r_n = 1 + \frac{H_c - h_c}{H_s - H_c} = 1 + \frac{t}{U} \quad \ldots\ldots\ldots [6]$$

For *completely regenerative* feedwater heating, that is, in a cycle in which the feedwater is heated to the saturated liquid enthalpy corresponding to the throttle pressure, the heat supplied is

$$\text{Heat supplied} = (H_s - h_s)(1 + w) \ldots\ldots\ldots [7]$$

and the heat rejected per pound of condenser flow is

$$\text{Heat rejected} = 1 \cdot (H_c - h_c) \ldots\ldots\ldots [8]$$

Then the heat rate r_s for a *completely regenerative* cycle is

$$r_s = 1 + \frac{(H_c - h_c)}{(1 + w)(H_s - h_s) - (H_c - h_c)} \quad \ldots\ldots\ldots [9]$$

For a cycle in which the feedwater is not heated to the saturated enthalpy corresponding to the throttle pressure, h_s is replaced by h, the enthalpy of the feedwater leaving the last heater.

[4] Exhaust loss will be considered later, since it is, in effect, an external loss. All of the following derivation is based upon "internal" heat rate, i.e., with no exhaust loss. The constant 3412.75 Btu per kwhr has been omitted throughout.

Subtracting Equation [9] from Equation [6], the reduction in heat rate is

$$r_n - r_s = \frac{t}{U}\left[1 - \frac{1}{1 - \left(\frac{R_s}{U}\right) + w\left(\frac{H_s - h_s}{U}\right)}\right] \ldots [10]$$

The fractional reduction then is

$$\frac{r_n - r_s}{r_n} = \frac{t}{U + t}\left[\frac{1}{1 - \left(\frac{U}{R_s - w(H_s - h_s)}\right)}\right] \ldots [11]$$

where all terms are known from the turbine efficiency and the assumed conditions, and w is as yet unknown.

Equation [11] may be rewritten as

$$\frac{r_n - r_s}{r_n} = \frac{t}{U + t}\left[\frac{w(H_s - h_s) - R_s}{w(H_s - h_s) - R_s + U}\right] \ldots [11a]$$

when heating to h_s in any number of heaters or

$$\frac{r_n - r}{r_n} = \frac{t}{U + t}\left[\frac{w_x(H_s - h) - xR_s}{w_x(H_s - h) - xR_s + U}\right] \ldots [11b]$$

when heating to h in any number of heaters.

These equations are strictly correct, providing the applicable value of w is used.

(Note that all of the heat rates mentioned are expressed in "Btu per Btu," the reciprocal of the thermal efficiency of the turbine cycle.)

It will be observed in the foregoing equations, which are general, that the gain over the nonextraction heat rate depends only upon the quantity of steam extracted per pound of condenser flow, the final feedwater enthalpy, the turbine efficiency, and the steam conditions. It may be generalized then, that with given steam conditions and turbine efficiency, the heat rate of a cycle depends only upon the fraction of the throttle steam extracted and the final feedwater enthalpy. This generalization may be carried even further: With given steam conditions, turbine efficiency, and final feedwater enthalpy, the heat rate of a cycle depends only upon the fraction of the throttle steam extracted. In other words, any change which reduces the amount of the extracted steam produces a poorer turbine heat rate. This change may, for example, be the use of more pressure drop between the turbine and the heater, or the use of a larger terminal difference in the heater. These two items both increase the difference between the enthalpy of the extracted steam and the feedwater leaving the heater, hence they reduce the quantity required to be extracted. Apparently, then, we need a method for calculating w, the total extraction.

Determination of w With an Infinite Number of Heaters

Assume that the condenser flow is 1 lb per hr. Then, for any infinitesimal contact heater, a heat balance may be set up

$$\text{Heat supplied} = \text{Heat required} \ldots\ldots\ldots [12]$$

or

$$dw_x(H - h) = dh(1 + w_x) \ldots\ldots\ldots [13]$$

Rearranging and integrating between the condenser hot well and the top heater to obtain w_x, the total amount extracted per pound of condenser flow

$$\log_e (1 + w_x) = \int_{h_c}^{h} \frac{dh}{H - h} \ldots\ldots\ldots [14]$$

To evaluate $\int_{h_c}^{h} \frac{dh}{H - h}$ let us use the Q.A., Equation [1]

$$(H - h) = ax^2 + bx + t$$

where

$$x = \frac{h - h_c}{h_s - h_c} = \frac{h - h_c}{R_s} \quad \text{[15]}$$

whence

$$dh = R_s dx \quad \text{[16]}$$

Equation [14] then becomes

$$\log_e (1 + w_x) = R_s \int_0^x \frac{dx}{ax^2 + bx + t} \quad \text{[17]}$$

or, when the right-hand member is integrated, changed to its simplest form, and the antilog taken

$$(1 + w_x) = \left(\frac{bx + 2t + x\sqrt{b^2 - 4at}}{bx + 2t - x\sqrt{b^2 - 4at}} \right)^{R_s/\sqrt{b^2-4at}} \quad \text{[18]}$$

In the case where $x = 1$, Equation [18] becomes

$$(1 + w) = \left(\frac{b + 2t + \sqrt{b^2 - 4at}}{b + 2t - \sqrt{b^2 - 4at}} \right)^{R_s/\sqrt{b^2-4at}} \quad \text{[18a]}$$

and w is equal to the right-hand member, minus 1.

Using Equations [18a] and [11a] and actual turbine state lines, a large number of calculations were made with great accuracy to determine the value of G, the gain with an infinite number of heaters heating to the saturation point. It is felt that fewer minor inconsistencies are introduced by calculation of the value of G along an actual turbine state line than by calculation of this value along an isentropic or 100 per cent efficiency line. The latter, although perfectly defined, never occurs in practice and its use would require additional correction, not only because of the abnormally low values of $(H - h)$, but also because it is a straight line, whereas normally, a curved state line is used.

The values of G are shown in Figs. 6 and 7, plotted against pressure for various temperatures, and in Fig. 8, plotted against temperature for various pressures. It was found that the variation of G with temperature is exactly linear as might be expected. Fig. 8(a) illustrates the variation in G, caused by departure from the base turbine efficiency of 80 per cent. Fig. 8(b) shows values of G plotted against back pressures higher than the usual range of condensing machines.

PART 3

The cycle which has been assumed in these studies is shown in Fig. 9, together with the nomenclature. We have used throughout this investigation that cycle which is most easily defined, and which is frequently approximated in practice, i.e., one in which the heaters have zero terminal differences and in which the rise in enthalpy per heater is constant and equal to

$$\frac{\text{Total rise in enthalpy}}{\text{Number of heaters}}$$

In practice the rises are usually very nearly equal, and any normally encountered departure from this situation does not affect the validity of the present analysis. The methods herein demonstrated make corrections for terminal difference, pressure drop, boiler-feed-pump work, heater distribution, etc., easily obtainable. It is the author's intention to present in a subsequent paper a method of using this analysis to determine the variation in heat rate with such minor variables as these, but it is not considered within the scope of the present paper to discuss them.

Determination of w_x With a Finite Number of Heaters

It has been shown necessary to calculate the extraction quantity. A determination of the extraction quantity with a finite number of heaters is made readily possible from the hypothesis that the rise in enthalpy per heater is constant, and equal to

$$\frac{\text{Total rise in enthalpy}}{\text{Number of heaters}}$$

Assume for the moment that $(H - h)$ is constant for all extractions and equal to

$$(H_c - h_c) = t \quad \text{[19]}$$

In this case

$$w_x = \sum_1^n E = \left(1 + \frac{R}{nt}\right)^n - 1 \quad \text{[20]}$$

This is a first approximation to the true quantity, but it is shown in the Appendix that a correction for the assumption that t = constant may be made. It is there shown that an approximate expression[5] for the actual total extraction is

$$w_x = \frac{t}{t + \Delta_w} \left[\left(1 + \frac{R}{nt}\right)^n - 1 \right] \quad \text{[21]}$$

where

$$\Delta_w = C_a ax^2 + C_b bx \quad \text{[22]}$$

or, inserting coefficients C_a and C_b, which are plotted in Fig. 10

$$\Delta_w = \left[\frac{(2n + 1)(n + 1)}{6n^2} + \frac{(n + 1)(n^2 - 1)}{12n^3} \left(\frac{R}{t}\right) \right] ax^2 + \left[\left(\frac{n + 1}{2n}\right) + \frac{n(n^2 - 1)}{12n^3} \left(\frac{R}{t}\right) \right] bx \quad \text{[23]}$$

Typical curves showing the variation of Δ_w with number of heaters and x are shown in Fig. 11, which has been drawn for 1200 psi, 900 F, 1 in. Hg. It will be noted that for one heater the value of Δ_w is equal to the value of $(ax^2 + bx)$. This is because, when one heater is used, the actual value of $(H - h)$ is that obtained from the plot of $(H - h)$ against x, the fractional rise. We have determined the constants a and b, so that

$$(H - h) - t = ax^2 + bx \quad \text{[1a]}$$

and when $n = 1$, C_a and C_b also become unity.

For two heaters at $x = 0.5$, it will be noted that the value of Δ_w is approximately equal to the average of the values read at $x = 0.25$ and $x = 0.5$. It differs from the exact average only because the extraction for the top heater is greater than the extraction for the first heater by a small amount (since the second heater is required to heat not only the condenser flow but also the extraction for the first heater).

Since we can obtain the reduction in nonextraction heat rate for any *finite* number of heaters from Equations [11b] and [21],

[5] This method obviously gives a second approximation to the extraction quantity with a finite number of heaters. To obtain the accuracy desired in the final results (Fig. 1) it was necessary for large values of $\frac{R}{n}$ actually to calculate heat balances, obtaining the values of $(H - h)$ from the Q.A. for consistency. If an accurate value of w_x is desired, it is suggested that Equation [24] be used, utilizing the curves of P and G which are strictly accurate, in preference to this second approximation.

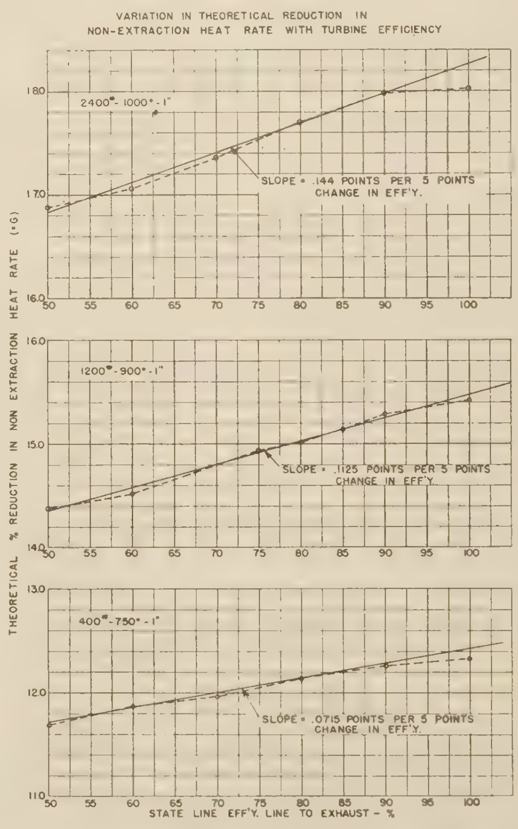

Fig. 8(*a*) Theoretical Percentage Reduction in Nonextraction Heat Rate for Typical Steam Conditions Versus Turbine Efficiency

and from Equations [11*a*] and [18*a*] we can obtain the reduction in nonextraction heat rate with an *infinite* number of heaters heating to h_s, it is possible to find the ratio of these two gains for any combination of rise, number of heaters, and steam conditions. This ratio is designated by P and plotted in Fig. 1.

Tables

In addition to the curves shown in Figs. 6, 7, and 8, Table 1 is presented showing the gains at various pressures and temperatures and for various vacuums, to two decimal places.

Table 2, of "Nonextraction Theoretical Heat Rates," will be found of great assistance when used with Figs. 14, 15, and 16.

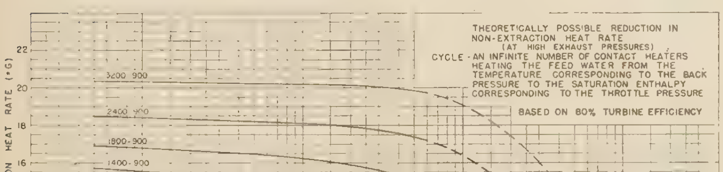

FIG. 8(b) THEORETICAL PERCENTAGE REDUCTION IN NONEXTRACTION HEAT RATE FOR TYPICAL STEAM CONDITIONS VERSUS EXHAUST PRESSURE

The table gives the heat rate of nonregenerative cycles operating with hypothetical turbines of 100 per cent efficiency. To obtain a quick estimate of actual heat rates:

1 Divide the nonextraction theoretical heat rate by the over-all nonextraction efficiency.

2 Obtain the gain due to feedwater heating by multiplying the ordinates of Fig. 14, and Fig. 15 or 16.

3 Apply this gain (as a reduction) to the nonextraction heat rate.

4 Reduce the resulting heat rate by from 1 to 2.5 per cent to allow for the reduction in exhaust loss, if a full-load heat rate is under consideration. (At lighter loads or with excessively large exhaust ends this nonthermodynamic gain will approach zero and may even become negative at very light loads due to loss in turbine efficiency with the reduction in exhaust flow resulting from extraction for feed heating.) More accurate calculation of the gain due to reduction in exhaust loss may be made using the method described in Part 7.

When the values of the percentage P of the theoretical gain G had been calculated, it was discovered that there was a small variation of corresponding points with respect to steam conditions. This variation can most logically and easily be related to a parameter A, as illustrated in Fig. 12, because the value of A is indicative of the history of the function $(H - h)$ between the condenser and the throttle, and uniquely determines the involved

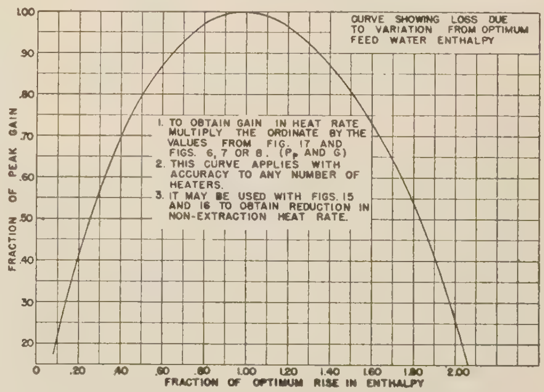

Fig. 14 Co-ordination of Shapes of Curves Shown in Fig. 1
(Fraction of peak gain plotted against fraction of optimum rise in feed-water enthalpy.)

variables, for a fixed state-line shape. Table 3 shows the values of a, b, and A as used in this investigation.

It will be noted in Fig. 13 that the variation of P with respect to A is small; hence for most purposes Fig. 1 may be used without this correction, especially for estimating. Fig. 13 is presented as a record and for the use of those who wish to take account of this secondary variation in the calculation of heat rates. Fig. 13(a) provides a convenient method of obtaining the value of A for any given conditions.

Partial-Load Heat Rates

As the load on a turbine decreases, there is a rapid drop in the rise, hence, the duty, of the lowest pressure heater. Occasionally,

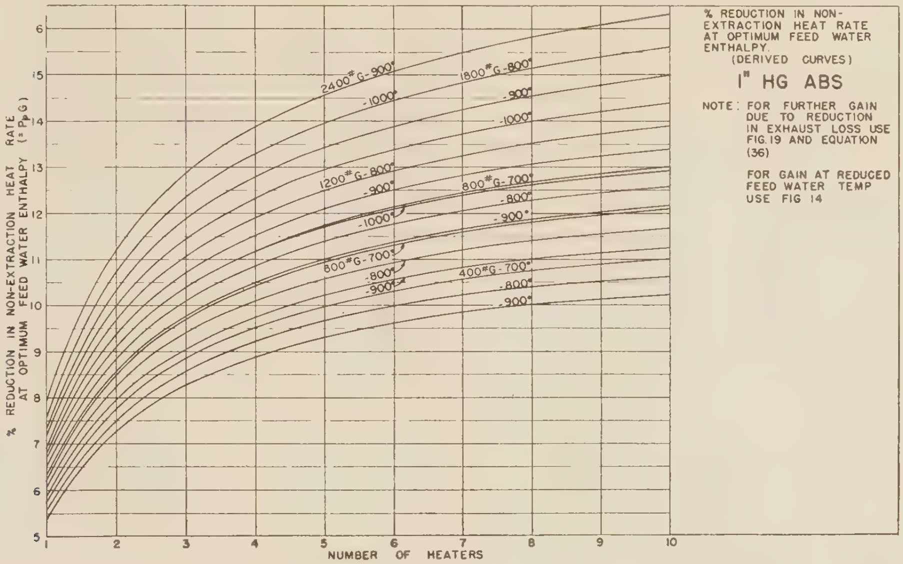

Fig. 15 Specific Curves Showing Actual Fractional Gain Over Nonextraction Heat Rate for Various Steam Conditions and Numbers of Heaters at 1 In. Hg Abs

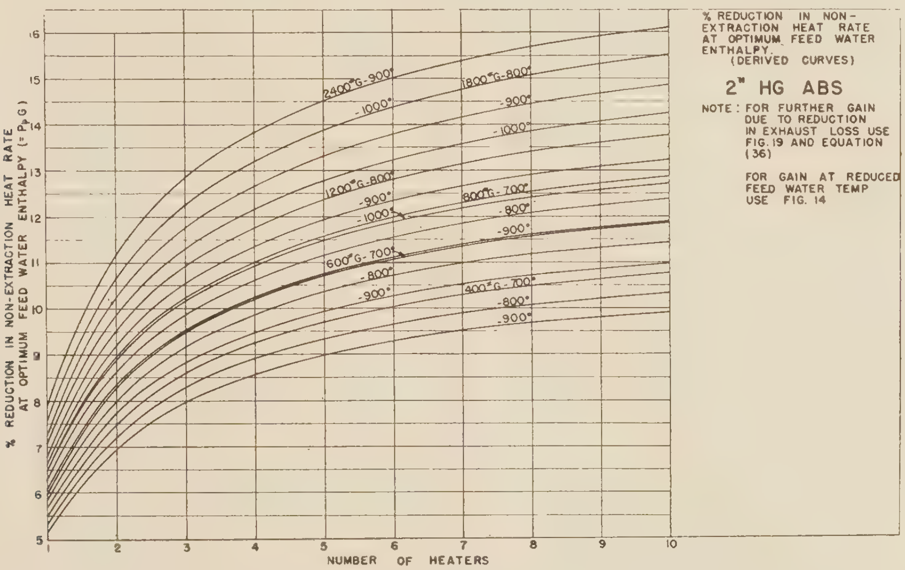

Fig. 16 Specific Curves Showing Actual Fractional Gain Over Nonextraction Heat Rate for Various Steam Conditions and Numbers of Heaters at 2 In. Hg Abs

where generator air coolers and steam jets are used in the condensate circuit, the extraction for this heater ceases to be required. At this point, the number of heaters obviously becomes $(n - 1)$. In the interval between normal load and this point, the effect of the progressive reduction in low-pressure-heater duty is equivalent to a reduction in the value of n, the number of heaters. In other words, in using Fig. 1, at partial loads, an interpolation should be made between n and $(n - 1)$. The reduction in duty of the low-pressure heater usually has little effect on the heat rate because of the convergence of the various lines in Fig. 1, at low fractional rises.

Due to the decrease in efficiency of the first stage at lighter loads, there is another small decrease in the gain, because of the concentration of output on the early stages with extraction operation. Several devices suggest themselves as a solution of this problem, if the user is unwilling to estimate the loss. One of the more easily understandable methods is to consider the initial pressure as that in the first stage, obtaining a heat rate by the method described herein. The first-stage output is then considered as being at 100 per cent thermal efficiency, and the heat rate reduced in proportion to the magnitude of this output. (Similar reasoning provides a method applicable to reheat cycles.)

PART 4

Specific Curves

The curves shown in Fig. 1 have been converted and plotted in Fig. 14, against percentage of optimum rise with percentage of

[a] $(A = {}^1/_3 a + {}^1/_2 b)$.
Based on 80 per cent turbine efficiency and 1 in. Hg abs back pressure.
To estimate A for other efficiencies and back pressures:
For each 5 points increase in turbine efficiency, increase the value of A by 12 Btu.
For each increase of 1 in. Hg, decrease the value of A by 6 Btu.

peak gain as the ordinate. There is a remarkable correlation between the shapes of these curves. Because of this probably fortuitous relationship, it is relatively easy to determine the gain for any cycle by reading from the derived curves, Fig. 15 or 16, the gain (P_pG) with the specified number of heaters at the peak feedwater temperature and for the steam conditions involved. For any value of the abscissa (fraction of optimum rise), in Fig. 14, the required factor on this gain may be determined.

It will be found that the curves, Figs. 15 and 16, are very useful in comparing cycles with various steam conditions and regenerative feedwater heating, when used with a table of theo-

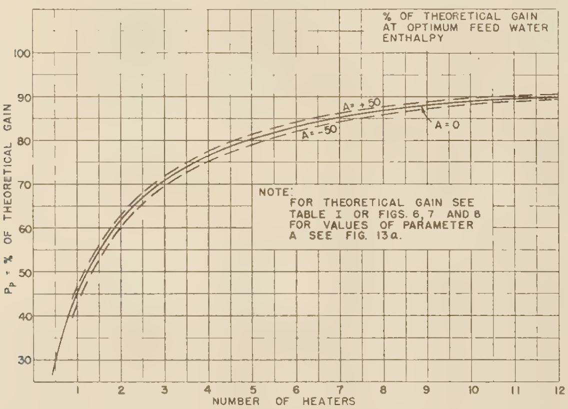

FIG. 17 FRACTION OF THEORETICAL GAIN OBTAINABLE WITH VARIOUS NUMBERS OF HEATERS WHEN HEATING TO OPTIMUM FEEDWATER TEMPERATURE

retical nonextraction heat rates, such as that shown in Table 2, using the method described in Part 3. Such calculations cannot take into account the variation in turbine efficiency, unless comparative nonextraction efficiencies are available. These efficiencies may be obtained by using the method described in a paper[6] by Warren and Knowlton.

Fig. 17 illustrates the variation in the percentage of the possible gain G, with the number of feedwater heaters employed. The ordinate of this curve, when multiplied by the value of G, obtained from Figs. 6, 7, 8, or Table 1, yields the gain over the nonextraction heat rate which is obtained by heating to the optimum feedwater temperature in various numbers of heaters. The percentage correction for change in the number of heaters may be determined by subtracting any two ordinates in Fig. 17, and multiplying by the value of G, obtained from Figs. 6, 7, or 8. (Observe that the result usually is required in percentage of the extraction heat rate; hence it must be divided by $[1 - PG]$.) Fig. 17 may also be used to determine the fraction of the total rise necessary to obtain peak gains, which is identical numerically with the value P_p.

Fig. 18 is presented as a method of determining the theoretically optimum feedwater temperature at various steam conditions.[7] Horizontal lines are shown in Fig. 18, from which the extraction pressure required may be determined. This extraction pressure is that which would be required with no pressure drop between the turbine and the heater and with no terminal difference.

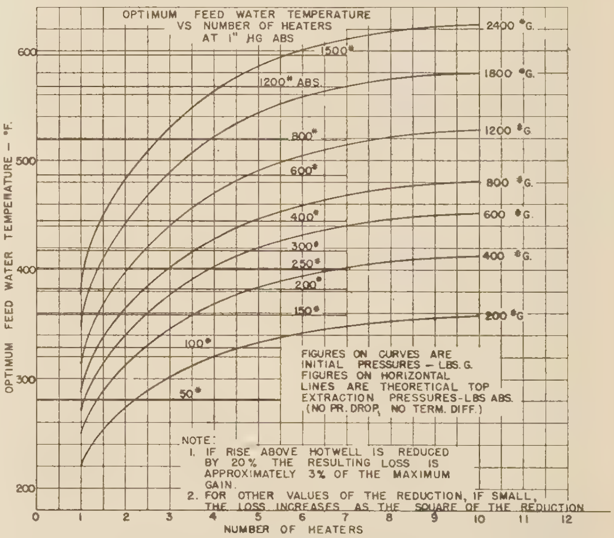

FIG. 18 THEORETICAL OPTIMUM FEEDWATER TEMPERATURE AT VARIOUS STEAM CONDITIONS VERSUS NUMBER OF HEATERS

(Horizontal lines indicate theoretical top extraction pressures with no terminal difference and no pressure drop. Add approximately 10 per cent to values shown to obtain true stage pressure.)

Under actual conditions, a slightly higher pressure must be used in order to compensate for these items (usually about 10 per cent higher pressure is required).

PART 5

DETERMINATION OF FRACTIONAL EXTRACTION

Occasionally it is desirable to determine directly the fraction of the total throttle flow extracted. The derivation of the expression is comparatively simple; hence only the result is presented herewith

[6] "Relative Engine Efficiencies Realizable From Large Modern Steam-Turbine Generator Units," by G. B. Warren and P. H. Knowlton, Trans. A.S.M.E., Feb., 1941, pp. 125–135.

[7] At first glance these feedwater temperatures may seem to be high. They are the exact peak of the curves in Fig. 1. In actual practice it is usually desirable to heat feedwater to somewhat less than these values for three reasons:

1 The loss in so doing is small as shown in Fig. 14.
2 The lower investment justifies this small loss.
3 Often, where a boiler economizer is used, the loss in boiler efficiency offsets the small gain which could be obtained with higher feedwater temperature.

Occasionally machines are sold with the anticipation of a low unit output factor. In these cases it may be desirable to approach or even exceed the theoretical feedwater temperature in order to affect favorably the light-load economy.

$\frac{w_x}{1 + w_x}$ = Fraction of throttle flow extracted

$$= \frac{R + \left[\left(\frac{PG}{1 - PG}\right)(H_s - h)\left(\frac{U}{t}\right)\right]}{U + t} \quad \text{..[24]}$$

This expression is useful in determining the additional gain due to reduction in exhaust loss as discussed subsequently. Under actual conditions, appropriate allowance should be made in the value of PG for the effect of terminal differences and pressure drop between the stage and the heater. This expression is strictly accurate, providing only that the value of PG is known, together with the true correction to PG for such small items as those mentioned.

PART 6

Reduction in Load Due to Extraction With Constant Throttle Flow

In many cases, it is desirable to determine directly the reduction in load due to extraction of steam for feedwater heating. An expression for the ratio of the loads with extraction and without extraction is derived as follows:

$$r_n = \frac{t + U}{U} \quad \text{......................[6a]}$$

$$r_e = \frac{(t + U - R)}{V} \quad \text{................[25]}$$

where V is the output per pound of throttle flow.

Then

$$\frac{V}{U} = \frac{\text{Extraction load}}{\text{Nonextraction load}} \quad \text{..............[26]}$$

with constant throttle flow.

Dividing Equation [25] by Equation [6a]

$$\frac{r_e}{r_n} = (1 - PG)\left(\frac{t + U - R}{t + U}\right)\frac{U}{V} \quad \text{.........[27]}$$

Solving for $\frac{V}{U}$

$$\frac{V}{U} = \frac{\left(1 - \frac{R}{U + t}\right)}{(1 - PG)} = \frac{\left(\frac{H_s - h}{H_s - h_c}\right)}{(1 - PG)} \quad \text{........[28]}$$

that is, the ratio of the internal output with extraction to the internal output without extraction is

$$\frac{\text{Internal extraction output}}{\text{Internal nonextraction output}} = \frac{1 - \left(\frac{R}{U + t}\right)}{(1 - PG)} \quad \text{...[29]}$$

assuming constant exhaust loss. The change in exhaust loss may also be considered as demonstrated in Part 7. Equation [29], including this change, becomes

$$\frac{\text{Net extraction output}}{\text{Net nonextraction output}}$$

$$= \frac{\left(\frac{1 - \frac{R}{U + t}}{1 - PG}\right)}{1 - \frac{\text{E.L.}_N}{\text{A.E.}}\left\{1 - F_1\left[1 - PG\left(\frac{t + U}{t}\right)\right]\right\}} \quad \text{...[30]}$$

(This expression has been simplified at a loss in accuracy of about 0.05 per cent, as is shown later.)

PART 7

Reduction in Heat Rate Due to Reduction in Exhaust Loss

The methods previously described provide the reduction in nonextraction heat rate accomplished thermodynamically by extracting for feedwater heating. In addition to the thermodynamic gain in thermal efficiency, resulting from regeneration, there is an additional gain which arises from the reduction in congestion of the flow in the exhaust passages. Although this gain is, in a sense, a reduction of an external loss, it is very real, and is intimately connected with the regenerative cycle.

The reduction in "exhaust loss" includes the reduction in kinetic energy of the steam leaving the last-stage buckets, as well as the reduction in pressure drop through the hood. (Exhaust loss is discussed at some length in Warren and Knowlton's paper.[6])

An expression, Equation [24], was given for the reduction in condenser flow resulting from extraction for feedwater heating

$$\frac{w_x}{1 + w_x} = \frac{R + \left[\left(\frac{PG}{1 - PG}\right)(H_s - h)\left(\frac{U}{t}\right)\right]}{U + t} \quad \text{...[24]}$$

By using this expression we are able to determine from Fig. 19 the ratio of the Btu exhaust loss.[8] The ratio of exhaust losses in

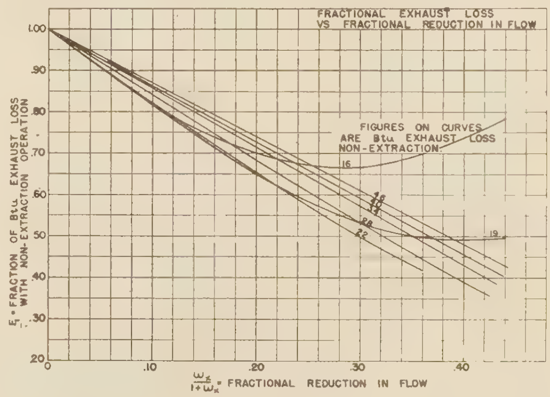

Fig. 19 Factor to Be Applied to Nonextraction Exhaust Loss in Btu to Obtain Extraction Exhaust Loss in Btu
(See part 7 in text for use of this factor.)

Btu is not the true ratio of the effective exhaust losses until it has been corrected in the ratio of the respective exhaust flows and loads for extraction and nonextraction operation.

The effective exhaust loss is defined by the equations

$$\text{Per cent E.L.}_N = 100 \cdot \frac{\text{E.L.}_N \times \eta}{U}$$

$$= 100 \cdot \frac{\text{E.L.}_N \times \eta \times \text{throttle flow}}{\text{Nonextraction load} \times 3412.75} \quad \text{.....[31]}$$

$$\text{Per cent E.L.}_e = 100 \cdot \frac{\text{E.L.}_e \times \eta \times \text{condenser flow}}{\text{Extraction load} \times 3412.75} \quad \text{.......[32]}$$

Observe that these equations are ratios of exhaust loss in kilowatts to output in kilowatts.

[8] These curves apply to exhaust ends as built for General Electric turbines, but will probably be found to hold without intolerable error for other designs.

Now let

$$\frac{\text{E.L.}_e}{\text{E.L.}_N} = F_1 = \text{ratio of Btu exhaust losses} \quad [33]$$

F_1 has been plotted against $\frac{w_x}{1 + w_x}$, the fraction of the throttle flow extracted, in Fig. 19.

Since the exhaust loss may be thought of as an external loss, directly affecting the turbine output, hence also the heat rate, but caused by internal phenomena, the heat rate is reduced by reduction in exhaust loss in the ratio

$$\frac{100 - \text{per cent E.L.}_N}{100 - \text{per cent E.L.}_e} \quad [34]$$

Using Equations [24] and [29] this ratio may be written

$$\frac{1 - \left(\frac{\text{E.L.}_N}{\text{A.E.}}\right)}{1 - \frac{\text{E.L.}_N}{\text{A.E.}} F_1 \left[1 - PG\left(\frac{t + U}{t}\right)\right]} \quad [35]$$

where A.E. = available energy.

For most purposes expression [35] may be used with slight error by converting it to a fractional reduction in heat rate due to decreased exhaust loss

Fractional reduction in heat rate due to reduction in exhaust loss

$$= \frac{\text{E.L.}_N}{\text{A.E.}} \left\{1 - F_1 \left[1 - PG\left(\frac{t + U}{t}\right)\right]\right\} \quad [36]$$

This reduction may then be applied to the heat rate

$$r_e = (\text{nonextraction W.R.})(H_s - h_c)(1 - PG)$$

$$\left[1 - \frac{\text{E.L.}_N}{\text{A.E.}} \left\{1 - F_1 \left[1 - PG\left(\frac{t + U}{t}\right)\right]\right\}\right] \quad [37]$$

(Mechanical and generator efficiency are assumed to be unchanged. If desired these may be handled separately.)

Appendix

Derivation of Expression for Quantity of Extraction With a Finite Number of Heaters

Let

$$(H - h) = ax^2 + bx + t \quad [1]$$

where $(H - h)$ is taken at any point along the state line.

If $a = b = 0$, then, with contact heaters, each succeeding heater must heat an increasing amount of feedwater, the increase being the amount of extraction which was added to the condensate flow at the preceding heater. In this case it will be seen that

$$w_x = \sum_1^n E = \left(1 + \frac{R}{nt}\right)^n - 1 \quad [20]$$

Since, in general

$$a \neq b \neq 0$$

it is necessary to apply a correction to Equation [20].

To obtain the correction let us expand Equation [20] by the binomial theorem

$$w_x = \sum_1^n E = \left[n\left(\frac{R}{nt}\right) + \frac{n(n-1)}{2!}\left(\frac{R}{nt}\right)^2 + \ldots\right] \quad [38]$$

This represents the total extraction from the turbine per pound of condenser flow. A similar expression may also be written for the total extraction up to and including the $(n - 1)$th heater

$$w_{\frac{n-1}{n}x} = \sum_1^{n-1} E = \left[(n-1)\left(\frac{R}{nt}\right) + \frac{(n-1)(n-2)}{2!}\left(\frac{R}{nt}\right)^2 + \ldots\right] \quad [39]$$

To obtain the extraction for the nth heater, subtract Equation [39] from Equation [38].

Extraction for nth heater

$$= \left[\left(\frac{R}{nt}\right) + (n-1)\left(\frac{R}{nt}\right)^2 + \ldots\right] \quad [40]$$

In similar fashion, the expression may be written for the extraction for any heater.

Because t has been assumed constant in Equation [20] and because the true value of $(H - h)$ exceeds the value of t by a small amount

$$\Delta_1 = ax_1^2 + bx_1 = ax^2\left(\frac{1}{n^2}\right) + bx\left(\frac{1}{n}\right) \quad [41]$$

the true value of the extraction for the first heater is

$$E_1 = \frac{t}{t + \Delta_1}\left[\frac{R}{nt} + 0\right] \quad [42]$$

$$= \left[1 - \frac{\Delta_1}{t + \Delta_1}\right]\left(\frac{R}{nt}\right) \quad [43]$$

In a similar fashion, the extraction for the second heater is given by

$$E_2 = \left[1 - \frac{\Delta_2}{t + \Delta_2}\right]\left[\left(\frac{R}{nt}\right) + 1\cdot\left(\frac{R}{nt}\right)^2\right] \quad [44]$$

and for the third heater by

$$E_3 = \left[1 - \frac{\Delta_3}{t + \Delta_3}\right]\left[\left(\frac{R}{nt}\right) + 2\cdot\left(\frac{R}{nt}\right)^2\right] \quad [45]$$

in which the second bracket is meant to indicate the complete series.

Equations [43], [44], and [45] may be rewritten in the following form (Equation [44] being taken as an example)

$$E_2 = \left[\left(\frac{R}{nt}\right) + 1\cdot\left(\frac{R}{nt}\right)^2\right] - \left[\frac{\Delta_2}{t + \Delta_2}\right]\left[\left(\frac{R}{nt}\right) + 1\cdot\left(\frac{R}{nt}\right)^2\right] \quad [46]$$

The total extraction w_x per pound of condenser flow will be the sum of all such expressions from E_1 to E_n, inclusive. Let us sum up from 1 to n expressions having the form

$$\Delta_2\left[\left(\frac{R}{nt}\right) + 1\cdot\left(\frac{R}{nt}\right)^2 + \ldots\right] \quad [47]$$

which in Equation [46] is the second bracket of the second term multiplied by the numerator of its coefficient.

The summation is

$$= ax^2 \left\{ \left(\frac{1}{n}\right)^2 \left[\left(\frac{R}{nt}\right) + 0 \cdot \left(\frac{R}{nt}\right)^2 \right] + \left(\frac{2}{n}\right)^2 \left[\left(\frac{R}{nt}\right) + 1 \cdot \left(\frac{R}{nt}\right)^2 \right] \ldots + \left(\frac{n}{n}\right)^2 \left[\left(\frac{R}{nt}\right) + (n-1) \left(\frac{R}{nt}\right)^2 \right] \right\}$$

$$+ bx \left\{ \left(\frac{1}{n}\right) \left[\left(\frac{R}{nt}\right) + 0 \cdot \left(\frac{R}{nt}\right)^2 \right] + \left(\frac{2}{n}\right) \left[\left(\frac{R}{nt}\right) + 1 \cdot \left(\frac{R}{nt}\right)^2 \right] + \ldots . \left(\frac{n}{n}\right) \left[\left(\frac{R}{nt}\right) + (n-1) \left(\frac{R}{nt}\right)^2 \right] \right\} \quad \ldots [48]$$[9]

which is readily seen to be

$$= ax^2 \left\{ \left(\frac{R}{nt}\right) \frac{(2n+1)(n+1)n}{6n^2} + \left(\frac{R}{nt}\right)^2 \frac{n(3n+2)(n+1)(n-1)}{12n^2} \right\} + bx \left\{ \left(\frac{R}{nt}\right)\left(\frac{n+1}{2}\right) + \left(\frac{R}{nt}\right)^2 \frac{n(n-1)(n+1)}{3n} \right\} \quad ..[49]$$

$$= ax^2 \left\{ \left(\frac{R}{t}\right) + \frac{n(n-1)}{2!n^2} \left(\frac{R}{t}\right)^2 \right\} \left\{ \frac{(2n+1)(n+1)}{6n^2} + \frac{(n+1)(n^2-1)}{12n^3} \left(\frac{R}{t}\right) \right\} + bx \left\{ \left(\frac{R}{t}\right) + \frac{n(n-1)}{2!n^2} \left(\frac{R}{t}\right)^2 \right\} \left\{ \frac{n+1}{2n} + \frac{n(n^2-1)}{12n^3} \left(\frac{R}{t}\right) \right\} \quad ..[50]$$

$$= \left[\left(1 + \frac{R}{nt}\right)^n - 1 \right] [C_a ax^2 + C_b bx] \text{ (approximately)} \quad ..[51]$$

Since the first factor of Equation [51] is the total extraction w_x, the second factor is an average weighted value of Δ, by virtue of the operation which was performed, that is

$$\Delta_w = ax^2 \left[\frac{(2n+1)(n+1)}{6n^2} + \frac{(n+1)(n^2-1)}{12n^3} \left(\frac{R}{t}\right) \right] + bx \left[\left(\frac{n+1}{2n}\right) + \frac{n(n^2-1)}{12n^3} \left(\frac{R}{t}\right) \right] \quad ..[52]$$

The value of the coefficients of ax^2 and bx, respectively, for various values of R/t are plotted in Fig. 10, against n, the number of heaters. The total extraction w_x then is

$$w_x = \frac{t}{t + \Delta_w} \left\{ \left[1 + \left(\frac{R}{nt}\right)^n \right] - 1 \right\} \text{ (in second approximation)} \quad \ldots . [21]$$

Knowing w_x, the fractional reduction in nonextraction heat rate, which can be obtained by feedwater heating, is seen to be that given in Equation [11*b*] in the text.

Parameter A

The parameter A (see Fig. 12) is defined as the area between the curve of $(H - h)$ and the horizontal line $(H_c - h_c) = t$ from $x = 0$ to $x = 1$. Since this curve is given by Equation [1]

[9] Two terms only of the series give excellent accuracy for the small correction function Δ_w.

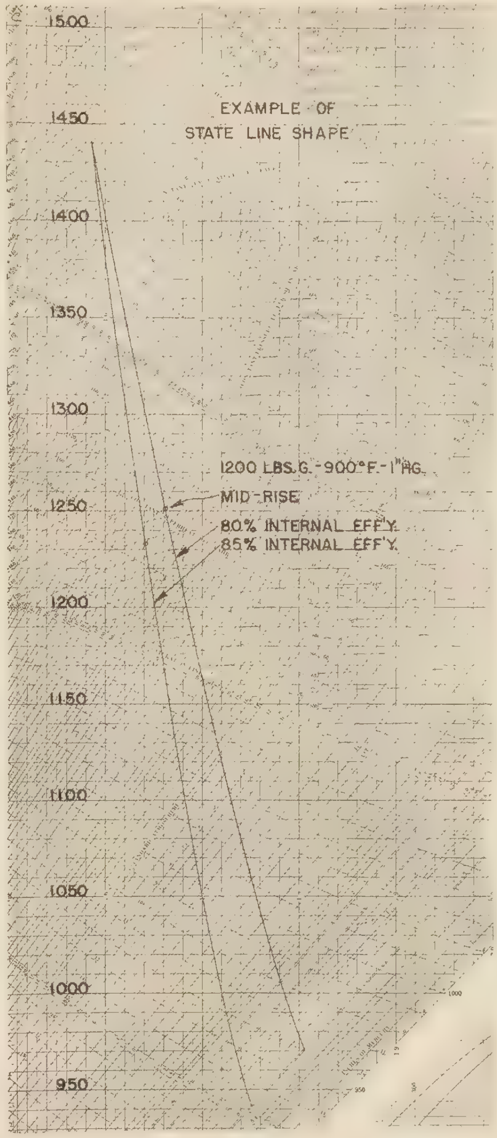

Fig. 20 Typical State Lines as Used in This Analysis

$$ax^2 + bx + t$$

the area under this curve will be

$$A = \int_0^1 (ax^2 + bx)dx$$

$$= \left[{}^1/_3 ax^3 + {}^1/_2 bx \right]_0^1$$

$$= {}^1/_3 a + {}^1/_2 b \ldots\ldots\ldots\ldots\ldots\ldots\ldots [53]$$

It should be mentioned that the correlation between A and the variation in P is dependent upon the use of a specific state-line curvature. A similar correlation might be worked out for any other shape of state line, which would be equally good but would differ by a small amount from that given. In practice, it has been found that a very flat curvature most nearly fits actual turbine state lines. This type of curve has been used in the analysis, and is illustrated in Fig. 20. Although the state line quoted in Warren and Knowlton's paper[6] is truly representative, in this

investigation, we have drawn it through the initial-state point, for purposes of consistency and accuracy of definition at all steam conditions. Obviously there is no appreciable difference in heat rate.

Correction for Actual Cycles

The P-x curves, of Fig. 1, are drawn for contact heaters and assume that the enthalpy leaving each heater is that of saturated liquid at the applicable temperature. For low feedwater pressures this is practically true. In recent years, with the advent of 1200-lb and higher pressure cycles, some engineers have considered the compressibility of the liquid in making heat balances, thus taking account of the recovery of part of the boiler-feed-pump input.

The major effect of the liquid compression is to reduce the extraction required from the next higher heater, thus offsetting part of the loss due to boiler-feed-pump power. In this paper no increase in liquid enthalpy due to liquid compression in any pump has been considered. A fairly accurate assumption, however, is that the boiler-feed-pump work is returned as heat to the cycle, and that for this reason the plant heat rate will suffer a fractional loss:

$$\text{Loss due to boiler feed pump} = \frac{\text{Boiler-feed-pump input}}{\text{Plant output}} \times (1 - \text{Cycle thermal efficiency}) \quad [54]$$

This modification is of the same character as that required by heater-terminal differences and pressure drop, and will be discussed by the author in a future paper.

As an interim approximation, the effect on heat rate of terminal difference and pressure drop aggregate in usual cases about 0.5 per cent in heat rate and may be so used. Evaporators, generator air or gas coolers, oil coolers, and steam-jet air-ejector condensers in the feedwater circuit can usually be taken care of separately if all the turbine data are known.

Example 1. What is an estimating heat rate for a plant operating at 800 psi gage, 900 F, 1 in. Hg, with six heaters? The nonextraction turbine efficiency is 81 per cent and the exhaust loss is 5 per cent.

Nonextraction heat rate from Table 2 $= \dfrac{8364}{0.81} =$ 10,326 Btu per kwhr

Gain from Fig. 15 = 11.38 per cent

Less cycle allowance 0.50

10.88 1123

9203 Btu per kwhr

Allow $2^1/_2$ per cent for decrease in E.L.[10] 230

8973 Btu per kwhr

If it is desired to heat the feedwater to less than the optimum enthalpy, an additional allowance, usually in the order of 0.25 per cent, should be added to this heat rate.

Example 1a. What is the true gain due to reduction in exhaust loss if the feedwater is 400 F?

$$R_s = 512.3 - 47.1 = 465.2$$
$$R = 375.0 - 47.1 = 327.9$$
$$x = \frac{R}{R_s} = 0.705$$

From Fig. 17, the optimum rise is at $x = 0.83$ (= 453 F)

$$\text{Fraction of optimum rise} = \frac{0.705}{0.83} = 0.849$$

From Fig. 14, fraction of peak gain = 0.983

$$0.983 \times 11.38 = 11.19$$

Less cycle allowance 0.50

10.69 per cent

Fractional extraction from Equation [24] =

$$\frac{327.9 + \left(\dfrac{10.69}{89.31} \times (1454.9 - 375)\ \dfrac{490}{917.8}\right)}{1407.8} = 0.282$$

$$\text{Btu exhaust loss, nonextraction} = 0.05 \times \frac{3412.75}{5.941^{11}} = 28.7 \text{ Btu}$$

From Fig. 19 and Equation [36], the fractional reduction in heat rate due to exhaust loss is

$$0.05 \left\{1 - 0.565 \left[1 - 0.1069 \left(\frac{1407.8}{917.8}\right)\right]\right\} = 2.64 \text{ per cent}$$

Hence, the heat rate in example 1 would have been 0.14 per cent better than calculated because of the slight error in exhaust-loss-gain estimate and about 0.21 per cent poorer because the feedwater temperature is below the optimum.

Example 2. Find the loss which may be expected if only four heaters are used in example 1, keeping the feedwater temperature constant.

From Fig. 1 at $x = 0.705$

$$P_6 = 81.6$$
$$P_4 = 76.2$$

$$\text{Gain with 4 heaters} = \frac{0.762}{0.816} \times 11.19 = 10.45 \text{ per cent (no cycle allowance)}$$

$$\text{Percentage increase in heat rate} = 100 \times \frac{0.74}{88.81} = 0.833 \text{ per cent}$$

Example 2a. Note that the same result may be obtained from Fig. 1 and Fig. 6, but that this method neglects the slight variation in P with the parameter A; whereas this variation is included in Figs. 15 and 16.

$$0.054 \times 13.58 = 0.733$$

$$\frac{0.733}{1 - (0.816 \times 0.1358)} = 0.825 \text{ per cent}$$

Example 2b. A further alternative is the use of Figs. 17, 6, and 14; providing the final feedwater is at the *same fraction* of the optimum rise, such as 84.9 per cent in example 1*a*

$$(0.835 - 0.769)\ 0.1358 \times 0.983 = 0.881 \text{ per cent}$$

$$\frac{0.881}{0.8885} = 0.992 = \text{loss at comparable feedwater temperature.}$$

Example 3. What is the approximate difference in heat rate between the plant in example 1, designed with four heaters, and a comparable plant designed for 1200 psi gage, 950 F, 1 in. Hg, 6 heaters, assuming there is no difference in turbine efficiency or exhaust loss?

[10] Experience will soon develop the ability to estimate this value quite accurately. In this case the large number of heaters makes the allowance higher than usual.

[11] "Theoretical Steam Rate Tables," by J. H. Keenan and F. G. Keyes, The American Society of Mechanical Engineers, New York, N. Y., 1938.

Use Table 2 and Fig. 15

$$\text{Plant } A \quad \frac{8364(1 - 0.105)}{\eta} = \frac{7486}{\eta}$$

$$\text{Plant } B \quad \frac{8015(1 - 0.1227)}{\eta} = \frac{7032}{\eta}$$

With 80 per cent turbine efficiency and an assumed gain of 2 per cent in exhaust loss in both cases

Plant A = 9170
Plant B = 8614

$$\text{Difference} = \frac{556}{9170} = 6.06 \text{ per cent plant } B \text{ is better than plant } A$$

whereas, nonextraction cycles would indicate only

$$\frac{349}{8364} = 4.17 \text{ per cent plant } B \text{ is better than plant } A$$

Actually plant B is probably slightly more than 6.06 per cent better than plant A, because of the greater reduction in exhaust loss resulting from a better heater cycle, providing the exhaust losses are equal on a nonextraction basis.

The difference in turbine efficiency would have to be applied to the result to obtain a true comparison.

Acknowledgment

The author wishes to express his indebtedness to Miss E. T. Hannan and Miss Daisy Houghton for the large number of numerical calculations made in obtaining data for the curves presented in this paper.

Experimental Studies of Automatic Control

By J. C. Peters,[1] Philadelphia, Pa.

It is important that new modes of automatic control and newly developed control mechanisms be proved in the laboratory, in so far as is possible. The first part of this paper describes an equipment for this purpose developed by the author's company during the last 10 years. Sufficient detail is given to be useful to others who may wish to build a similar equipment. The second part of the paper deals with typical results obtained, illustrated with actual test records.

It is important that field studies of automatic control be carried out with minimum disturbance to the controlled process. With modern high-capacity units, unnecessary shutdowns or loss of production, even for short periods, cannot be tolerated. In the refining industry, for example, neither operators nor management look with favor upon repeated changes in furnace or tower temperatures made just to learn how a controller will take care of them. It is, therefore, the responsibility of the manufacturer of control equipment to prove his product in the laboratory, in so far as is possible, before trying it out on an actual job. A suitable "dummy" process used for this purpose by the author's company will be described, together with examples of results obtained. Sufficient detail will be given to be useful to others, particularly teachers of instrumentation courses, who may wish to build a similar equipment.

Description of Laboratory Process

The principal elements of the laboratory process are shown in Fig. 1. While it is one involving temperature control only, it is proper to say at this point that the fundamentals of control are much the same regardless of the particular controlled variable involved. Peculiar to temperature control is the unfavorable effect of "transfer lag," which may be defined for present purposes as retardation, resulting from intervening thermal resistance, in the effect, at the point of measurement, of changes in the adjusted heat supply. Another unfavorable process lag, "distance-velocity lag," found particularly in pH control, can be introduced into the temperature process by a suitable artifice to be described later. In short, a temperature process is most convenient for general automatic-control studies.

Referring to Fig. 1, the automatic controller under test maintains temperature in a small tank[2] of water *B*. The controller adjusts rheostats to provide the proper rate of electric heating in a nichrome winding surrounding the tank. The heat output of this winding will be spoken of as the "supply." The "demand" will refer to the heat required by a flow of water which enters at *F* and overflows at *G*. A manually adjustable head device is provided so that the demand may be changed at will and the resulting control action observed.

The degree of difficulty of control is determined by the thermal relationship between the heater winding and the tank. A bare heater winding, immersed in the water, would result in such an easy process to control that special tests of it would not be worth while. By isolating the heater thermally from the tank to a certain extent, the control problem can be made just as difficult as is desired. In the particular arrangement shown, the tank is first covered by about $^1/_8$ in. of asbestos sheet. The winding is then applied and on this is placed a layer of alundum cement, followed by glass wool. Typical test records to be given later will show the extent to which transfer lag affects control with this construction.

While an equipment of the type shown is simple in principle, unless considerable care is taken in the design, spontaneous changes in supply or demand will occur to obscure the results. On the supply end, line-voltage variations represented a considerable source of annoyance, until voltage regulators were applied, practically eliminating the trouble.

The scheme shown in Fig. 1 for handling the demand flow was evolved after various others were proved to be undependable. In this, every precaution was taken to eliminate the trapping of gas liberated from the water by heating.

Tank *A* is the source of water for the demand flow. Here the temperature is held at 50 C, using a contacting mercury thermometer with a special relay. Because the return flow is at a higher temperature, a fixed water flow through a closed coil is provided to make it possible to control by heating.

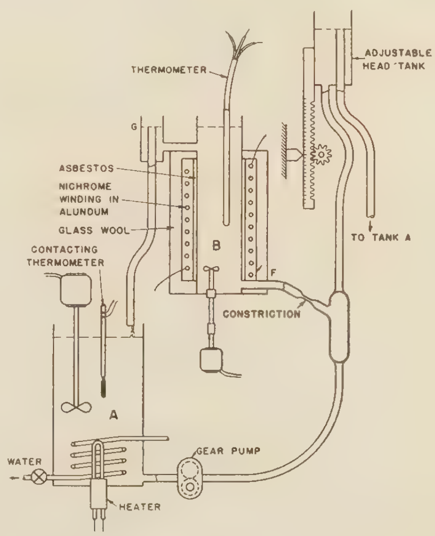

Fig. 1 Schematic Representation of Laboratory Process

A gear-type constant-displacement pump is induction-motor-driven to circulate approximately 40 cu in. of water per min. By setting the height of the adjustable head device, the water flow through *B* may be varied as desired. By tapping off for the useful flow as indicated, most of the liberated gas is carried directly through the system and passes out at the overflow in the variable head device. The expanded section near the tap-off point was introduced to eliminate the effect of eddies, which caused some change in the effective head, with normal variations in total flow, resulting from variable "slippage" in the pump.

[2] Diameter 2.5 in., water depth 9 in., water capacity 44 cu in.

Contributed by the Committee on Industrial Instruments and Regulators of the Process Industries Division and presented at the Semi-Annual Meeting, Kansas City, Mo., June 16–19, 1941, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

The constriction in the line to tank B is of a transparent plastic in which any stoppage is readily observed. Distilled water is used to cut down accumulation of solids in the closed system.

The power circuit for the heater of tank B is shown in Fig. 2, together with means for positioning the rheostats in response to air pressure, as is required when a pneumatic controller is under test.

For test purposes it is convenient to have a linear relationship between rheostat position and power input to the heater. This relationship is closely obtained with the connection scheme shown. Resistance values, as indicated, are for use with a heater of 19 ohms resistance. The available power range is 40 to 660 w.

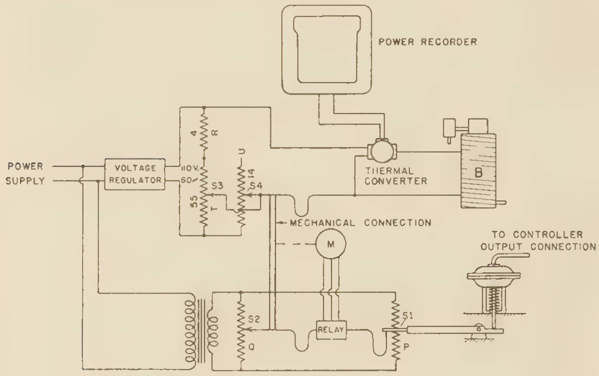

Fig. 2 Heater Circuit and Scheme for Positioning Rheostats in Accordance With Air Pressure

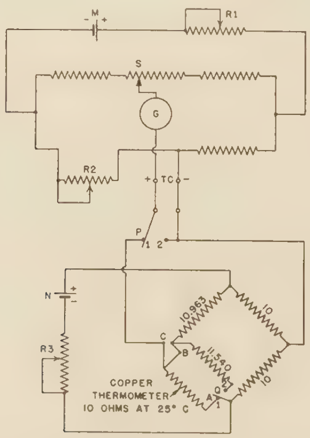

Fig. 3 Scheme for Using a Potentiometer Recorder With a Resistance Thermometer

As indicated by the rigid connection, contacts $S2$, $S3$, and $S4$ always move together. The positions of these contacts are caused automatically to follow that of contact $S1$ on slide-wire P. Unless the Wheatstone bridge consisting of the parts of rheostats P and Q is balanced, a suitable contact is made in the differential relay to energize the motor which moves contact $S2$ to restore the balance.

In testing electrical control mechanisms, slide-wire P and the relay may be part of the controller under test. In testing pneumatic controllers contact $S1$ is moved by a diaphragm motor as indicated. An 11-in. diaphragm motor with valve positioner attached is provided.

Tank B is large enough to take mercury-filled- or vapor-pressure-type bulbs of suitable temperature range. With either resistance-thermometer- or thermocouple-type instruments, a resistance thermometer is used as the primary element. This is because the desired temperature range does not give enough sensitivity with thermocouples. The recorder range generally used is 50 to 80 C. A suitable auxiliary circuit, adaptable to a thermocouple potentiometer of almost any range, is shown in Fig. 3.

Referring to Fig. 3, the points marked TC, + and —, represent thermocouple terminals of a potentiometer recorder, the circuit of which is shown above these points. In this circuit, the nickel coil which provides for automatic reference junction compensation has been replaced by an adjustable resistance $R2$ of manganin, which should have a range of about 10 ohms in increments of 0.01 ohm.

Below the TC terminals is shown an unbalanced bridge arrangement providing an emf dependent upon the temperature of a copper resistance thermometer. The adjustment procedure is as follows:

First, the TC terminals are shorted by throwing switch P to position 2, and resistance $R2$ is adjusted until the recorder balances at the low end of the scale. The recorder circuit is then standardized against the standard cell (not shown) in the usual manner. Switch P is now thrown to position 1 and switch Q to position 2. Rheostat $R3$ is then adjusted until the recorder reads 65 C as it should, since 11.540 ohms is the resistance of the thermometer at this temperature. Because 10.963 ohms is the resistance of the thermometer at 50 C, and because $R2$ was adjusted for zero emf at the low end of the scale, this end of the scale will correspond to 50 C.

It should be noted that a highly accurate temperature scale is not necessary for the purpose of testing automatic controllers.

Figs. 4 and 5 are front and rear views, respectively, of the actual equipment. In Fig. 4 three rheostats are seen on the table to the left. Two of these in parallel constitute rheostat U of Fig. 2. Rheostat Q is not seen in Fig. 4, as it is behind the others. It is of a small rotary type, driven through a worm from one of the larger rheostats. The voltage regulators, two 500-w units in parallel, are seen under the rheostat table.

On the second table is seen tank B with the mark LN. What is seen is not the tank proper but a brass cylinder surrounding it. To the right of tank B is the adjustable head device. The large tank, mounted through a hole in the table, is tank A of Fig. 1. To the right of tank A and under the table is the No. 2 Oberdorfer gear pump, driven through a worm reduction at a speed of approximately 90 rpm.

The recorder on the left-hand side of the panel board is the power recorder of range 0–1000 w. Under this is a push-button station for use when it is desired to position the rheostats manually through operation of the motor. The differential relay is flush-mounted in a case below the push buttons.

The pneumatic control instrument on the right-hand side of the panel is used for general automatic-control studies and as a recorder only, when other controllers are being tested. It is provided with a Wheatstone-bridge circuit for the range of from 50 to 80 C.

Controllers under test are mounted either on the slat-type board seen at the extreme right or on a similar board, out of the view, on the left. The switching scheme is such that two controllers, one a pneumatic and the other an electric type, may be applied alternately without changing the wiring.

In the rear view, Fig. 5, the diaphragm motor for positioning rheostat P of Fig. 2 is seen at the left. To the right, on the corner of the table, is a small magnetic brake used to stop motion of the rheostats quickly.

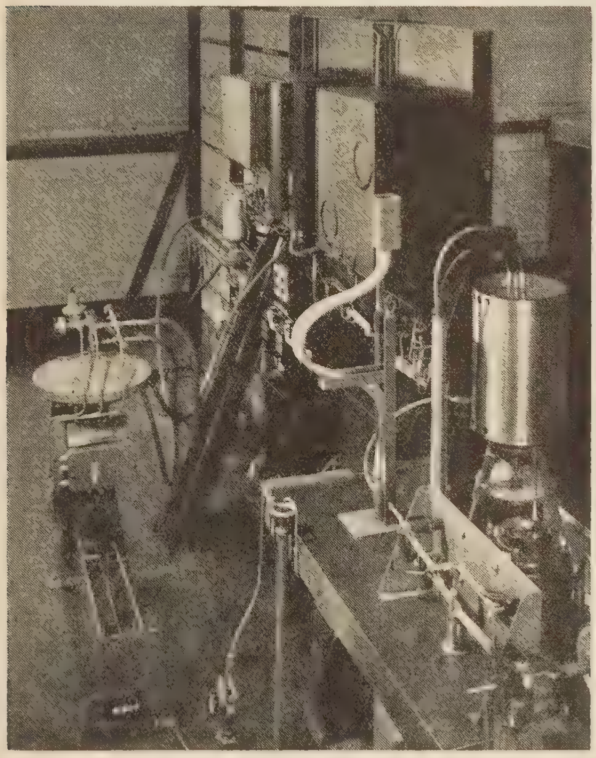

Fig. 5 Rear View of Automatic-Control Test Equipment

Experimental Results

The illustrations which follow are all reproductions of photographs of actual test records. To simplify the marking of the records it will be mentioned here that, in all cases, the vertical scale is time, each scale division representing 10 min, and higher points are for later times; for temperature records, each scale division is 0.5 deg C, and for power records, each scale division represents 10 w.

(*a*) *Process Characteristics.* Figs. 6(*a*) and (*b*) show temperature-response curves, resulting from sudden changes in demand and supply, respectively. Changes were made at the times indicated by the arrows. The response to sudden demand

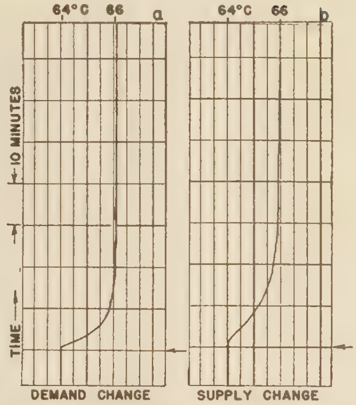

Fig. 6 Response of Process to Sudden Change, No Automatic Control

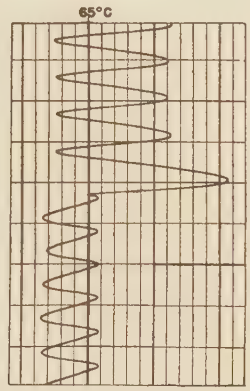

Fig. 7 Two-Position Control Record, Showing Effect of Sudden Demand Change

change, e.g., a sudden decrease in rate of water flow, was evident on the record 40 sec after the change was made and the response was 60 per cent complete in 220 sec.

The response to a sudden supply change, e.g., change in rheostat position, was evident on the record in 90 sec, and the time required for the change to be 60 per cent complete was 645 sec.

Delay in the initial response to a demand change is mainly the result of detection lag in the resistance thermometer used, this particular element not being of a very rapid type.

(*b*) *Two-Position Control.* Fig. 7 shows the results obtained with two-position control under two different conditions of demand. The power changed between 40 and 660 w as the temperature crossed the 65-deg value. For the first portion of the curve, the power is at 660 w 79 per cent of the time, and at 40 w 21 per cent of the time, giving an average power of 530 w. After the decrease in load the average power is 235 w.

(*c*) *Proportional-Plus-Floating Control.*[3] The significance of the series of curves which follow will be evident after a discussion of the typical curves of Fig. 8. Curve 8(*a*) is the temperature response to a sudden change in demand, i.e., a sudden change in the rate of water flow through tank *B*, with proportional-plus-floating control. First the demand was increased, then 40 min later, it was decreased. Curve 8(*b*) is the corresponding record of

[3] This may be more completely specified as proportional-position plus proportional-speed-floating control. Refer to "Some Fundamental Considerations in the Application of Automatic Control to Continuous Processes," by E. S. Bristol and J. C. Peters, Trans. A.S.M.E., vol. 60, 1938, pp. 641–650.

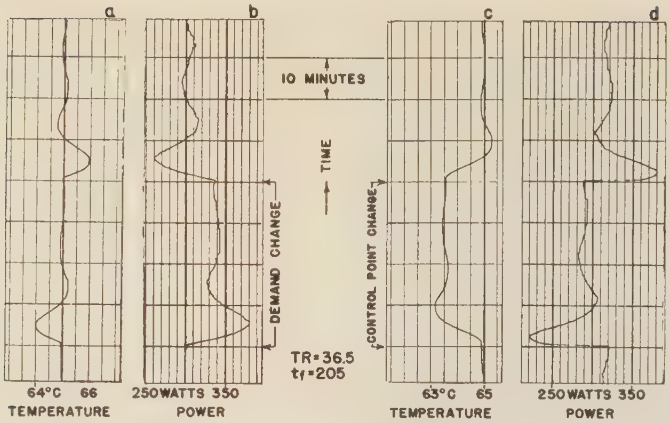

Fig. 8 Typical Responses to Sudden Demand and Control-Point Changes

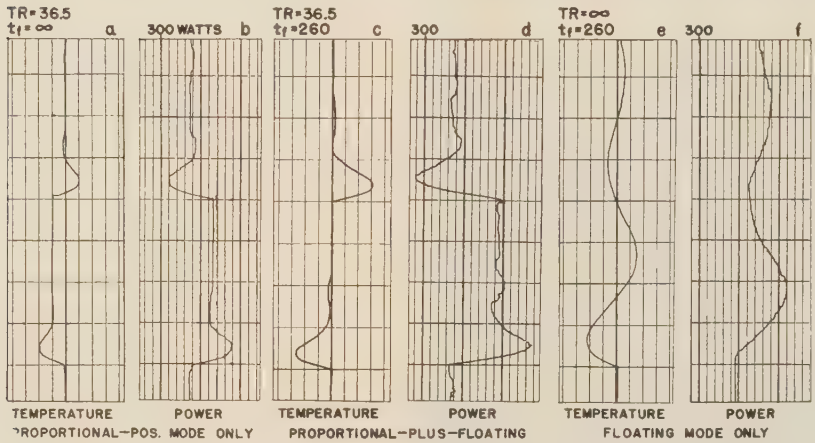

Fig. 9 Effect of Cutting Out Either Component Mode in Proportional-Plus-Floating Control

power to the heater. From this it will be noted that the load change required an ultimate power change of 40 w.

Curve 8(*c*) is the temperature response to a sudden change in control point, the controller adjustments being exactly the same as for 8(*a*). For 8(*c*) the water flow was left unchanged but the control setter was moved for control at 63.5 C and then, 40 min later, turned to the original setting of 65 C. With the particular controller used, and this would be the case with most controllers operating in accordance with the same mode of control, the proportional-position action functions as soon as the setting is changed and shifts the power as though the temperature had deviated from the control point by the amount of the change in setting. The power record of curve 8(*d*) shows this effect followed by additional change due to the combined proportional-position and floating actions.

For these and records which follow, the TR (throttling-range) value is the apparent percentage of the scale range, 9.875 in., or 50 to 80 C, through which the pen would have to be moved to change the power over the entire adjustable range of 40 to 660 w. It is determined in the following manner:

With the power in the vicinity of the range covered in a particular test, the pen is moved by a small amount, say ΔS per cent of the scale range. The corresponding power change by proportional-position action only is noted. Calling this ΔP, the TR value is then calculated from the formula

$$TR = (660 - 40) \times \frac{\Delta S}{\Delta P}$$

The "floating time" t_f is the apparent time in minutes required to change the power through the entire adjustable range by floating action alone, when the deviation from the control point is 1 per cent of the scale range. This is determined by noting the power change ΔP_1 occurring in a given time t, when the deviation is ΔD per cent of the recorder scale range. Then

$$t_f = (660 - 40)\ \frac{\Delta Dt}{\Delta P_1}$$

This figure applies to the throttling range used in the particular test. Generally and preferably, a change in throttling-range setting changes the floating time proportionately. If the floating-speed adjustment remains fixed, then

$$\frac{t_f}{TR} = \text{constant}$$

The value of this ratio is, therefore, an index of the setting for floating speed, and is inversely proportional to it.

The curves of Fig. 9 show what happens when one of the component modes of proportional-plus-floating control is cut out. Curve 9(*c*) is the response to a sudden demand change with proportional-plus-floating control adjusted so that the return to the control point is nearly "critically damped," i.e., it takes place about as rapidly as is possible without overshooting. Curve 9(*d*) is the corresponding power record.

Curve 9(*a*) was obtained with the floating action cut out. While the control is stable, the temperature is not returned to the

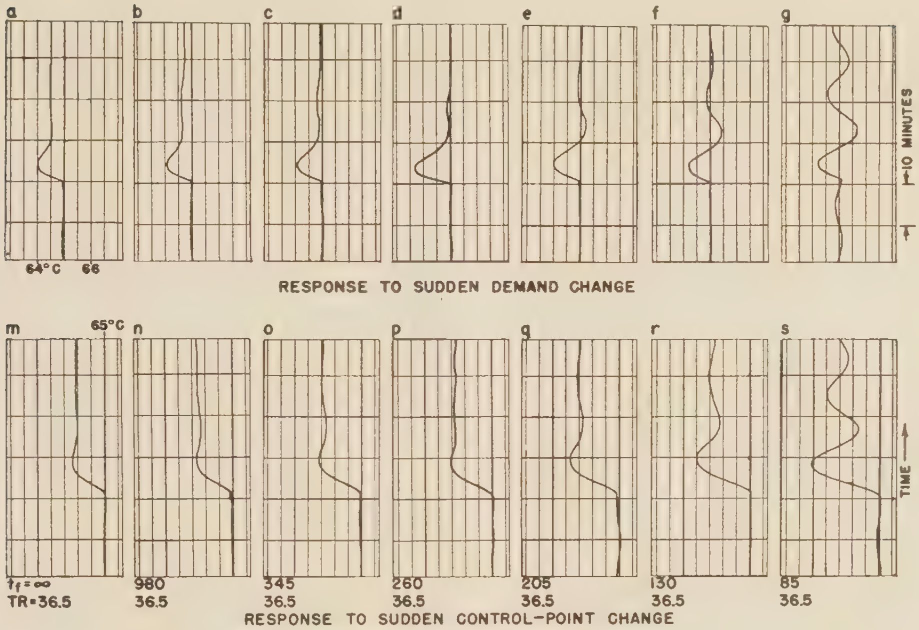

Fig. 10 Effect of Floating-Speed Adjustment

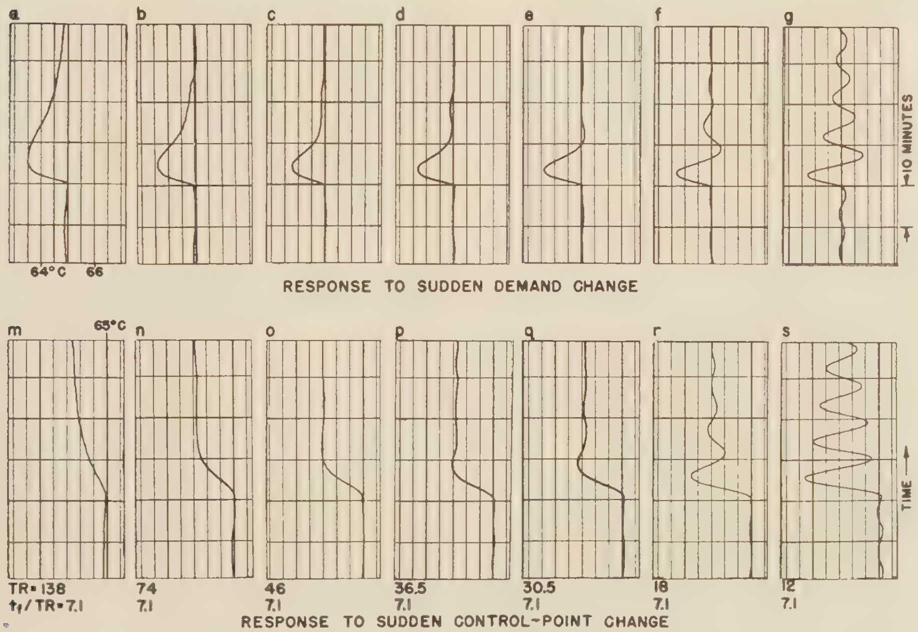

Fig. 11 Effect of Throttling-Range Adjustment

initial value. In curve 9(e), with floating action only, return to the control point is seen to be taking place after a series of oscillations, the first overshoot being 70 per cent of the initial deviation. In comparing 9(b), (d), and (f), it should be noted that ultimate power shifts are not equal but have values of 30, 55, and 35 w, respectively, representing demand changes of different magnitudes.

The curves of Figs. 10 and 11 show how varying the adjustment of floating speed and throttling range affects the responses to sudden change of demand or of control point. Curve 10(d) is for adjustment giving a nearly critically damped response to demand change and 10(p) is the response to control point change obtained with the same controller adjustments. To the left of these are curves obtained with slower floating speeds or longer floating times, while the curves to the right are for more rapid floating action. For curve 10(a) there is no floating action and, as would be expected, the temperature does not return to the original value. In 10(b), the return is so slow that a record of several times the length given would be needed to show when it is nearly complete.

It is to be noted that the small oscillations about the return

curve, as seen in records 10(*b*), 10(*c*), and 10(*d*), are due to the proportional-position mode and could be removed by widening the throttling range slightly. The floating speed is adjusted correctly when this action is just sufficient to center the oscillations about the control point. In curve 10(*d*), the floating action is slightly less than sufficient.

By comparing the results of sudden control-point changes with those of sudden demand changes, it will be seen that characteristics as regards slow approach to final temperature or conditions of damped oscillation are similar. Frequently, the safest way to study the action of a controller, applied in the field, is to make small control-point changes and note the results.

In Fig. 11 curves (*d*) and (*p*) are identical with the correspondingly lettered curves of Fig. 10. The curves on either side of

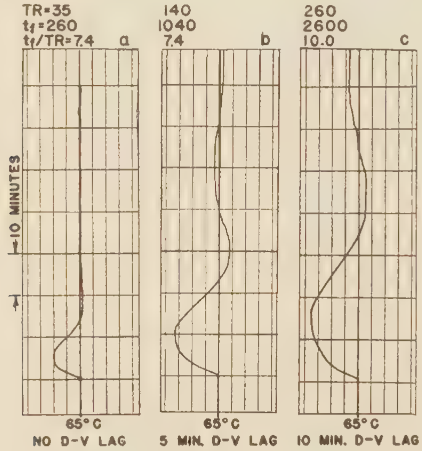

Fig. 12 Effect of Distance-Velocity Lag

11(*d*) and 11(*p*) show the effect of varying the throttling-range setting. As previously stated the floating time varies directly with the throttling-range setting.

As with the setting for floating speed, too weak an action means sluggish return and too strong an action introduces undesirable oscillations. Comparing 10(*d*) and 10(*f*) with 11(*d*) and 11(*f*), each representing an increase in strength of 50 per cent in the control action, it is seen that the decrement of the resulting oscillation is greater for a 50 per cent decrease in throttling range than it is for the same percentage reduction in floating time.

The temperature-response curves of Fig. 12 show results obtained with proportional-plus-floating control when distance-velocity[4] lag is introduced. This type of lag represents a definite delay between the time when a change takes place at the point at which the controlled variable should be held constant and the time when the controller is in a position to do something about it. In pH control, it is the time required for the solution to travel from the point at which a control agent is added to the point at which the electrodes for measurement are located.

In using a temperature-controlled process[5] for studies of the effect of distance-velocity lag, an artifice must be used to give a similar effect. The procedure which we have followed is to actuate the control mechanism from a pointer which is moved manually to follow the temperature curve, as produced at a specified previous time.

In Fig. 12 curve (*a*) is the response without distance-velocity lag. For curve (*b*) the lag is 5 min, and for curve (*c*) it is 10 min. Upon introducing the *D-V* lag of 5 min, the control was found to be unstable until the throttling range was widened. Upon changing the *TR* setting from 35 to 70 per cent (record not shown), the control was stable but the first overshoot was twice that of curve (*b*). A wider throttling range than the 140 per cent figure used for curve (*b*) would further reduce the oscillations.

Curve 12(*c*) shows that stable control is possible with a 10-min *D-V* lag, but it is required that the control actions be further weakened. In considering automatic control in the face of *D-V* lag, the point made by Callender and Stevenson[6] must be clearly kept in mind, namely, that any changes which occur during the delay period are inevitable. If means can be introduced to keep these within allowable limits, then satisfactory control may be obtained in spite of the lag.

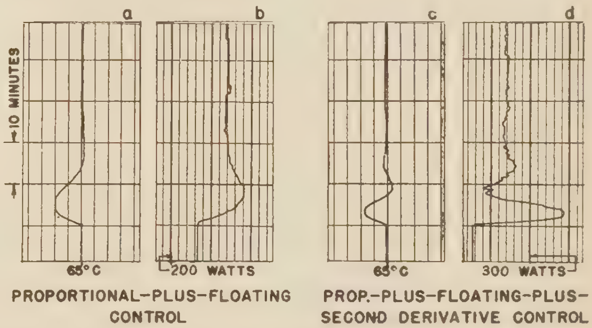

Fig. 13 Curves Showing Effect of Adding Second-Derivative Mode

The effect of the addition of the second-derivative[7] mode of control to proportional-plus-floating control is illustrated by the curves of Fig. 13. Before discussing the curves, what is meant by second-derivative control will be explained. If we consider the action of the control valve (or rheostat) at any instant, the floating mode may be said to move the valve at a rate proportional to deviation from the control point, while the proportional-position mode simultaneously moves it at a rate proportional to the rate of change of the deviation with time. The second-derivative mode causes valve motion at a rate proportional to the rate of change of the rate of change of the temperature deviation, i.e., in accordance with the rate at which the slope of the temperature curve is changing. The resultant rate of valve movement is described by the equation

$$-\frac{dV}{dt} = A\theta + B\frac{d\theta}{dt} + C\frac{d^2\theta}{dt^2}$$

where V = valve position
θ = deviation of temperature from control point
A = a constant for floating action

[4] The term "distance-velocity lag" is preferred to the term "velocity-distance lag" originally suggested by C. E. Mason in his paper, "Science of Automatic Control in Petroleum Refining," *World Petroleum*, vol. 4, 1933, pp. 187–190. This is because the changed order of the words is more suggestive of the ratio of distance to velocity which has the dimensions of time, in numerical units of which this lag can usually be stated.

[5] Distance-velocity lag, referred to by another name, was introduced in a laboratory process for the study of pH control by J. J. Grebe, R. H. Boundy, and R. W. Cermak and is described in their paper, "The Control of Chemical Processes," Trans. American Institute of Chemical Engineers, vol. 29, 1933, pp. 211–256.

[6] "The Application of Automatic Control to a Typical Problem in Chemical Industry," by A. Callender, and A. B. Stevenson, Proc. of the Chemical Engineering Group, Society of Chemical Industry (London) vol. 18, 1936, pp. 108–116.

[7] This name arises from the fact that this mode is represented by a second-derivative term in the differential equation to be given shortly. Perhaps "rate-of-rate" control would be a more acceptable name for it.

B = a constant for proportional-position action
C = a constant for second-derivative action

Comparing temperature curves 13(a) and 13(c) it is seen that with second-derivative control the temperature is brought to within 0.2 C of the control point in 6.5 min, while without this mode the time required was 12 min. Power records 11(b) and 11(c) show clearly how the power is more quickly increased when second-derivative control is used and how it is cut back sharply to prevent serious overshooting.

While second-derivative control is the subject of several patents[8] and has been discussed in papers on automatic control, it has never been widely used. The chief factors in this have probably been the complication of most mechanisms proposed for the purpose, and the problem involved in making adjustments to fit the controller to a particular application. The combination of proportional-plus-floating plus second-derivative control requires the manipulation of three separate adjustments to fit it to the job.

Acknowledgment

In conclusion the writer wishes to express his appreciation to Mr. E. W. Yetter for his assistance, both in obtaining test records and in assembling material for the paper.

Discussion

N. B. Nichols[9] and J. G. Ziegler.[10] The writers have developed a method of predicting optimum controller settings, and the data contained in this paper afford a trial of this method. This method will be described in a paper now in preparation. By optimum settings, we mean such adjustments of the controller response as will give a reasonable combination of small deviations from, and prompt return to, the control point. The data needed could be obtained from a study of the uncontrolled-process-response curve shown in Fig. 6(b) of the paper, but unfortunately the author does not give the magnitude of the supply change causing this response curve. However, they may also be obtained from the curves shown in Fig. 7. Using the writers' method on the larger load (bottom half) of Fig. 7, it may be predicted that the following controller settings would give good control

$$TR = 10 \text{ per cent}$$

$$t_f = 58 \frac{\text{Min}}{\text{Per cent}} \qquad \frac{t_f}{TR} = 5.8 \text{ min}$$

Using the small load (upper half) of Fig. 7

$$TR = 24 \text{ per cent}$$

$$t_f = 180 \frac{\text{Min}}{\text{Per cent}} \qquad \frac{t_f}{TR} = 7.5 \text{ min}$$

From these data, it would appear that the process is slightly easier to control at larger loads. Since it appears that most of the author's curves are run with loads of less than 540 w, we shall use the latter values. It will be observed that these values correspond to a controlled-response curve about halfway between the curves of Fig. 11(e) and 11(f), 11(q) and 11(r). It thus appears that for this example our method has predicted settings which give good control. Evidently, the author has not made the same load change in the various controlled-response curves given in Figs. 10 and 11. We believe a better comparison could be made if the relative magnitudes of the load changes were known.

In the examples with distance-velocity lags our method would predict the following settings:

Distance-velocity lag of 5 min

$$TR = 80 \text{ per cent}$$

$$t_f = 1900 \frac{\text{Min}}{\text{Per cent}} \qquad \frac{t_f}{TR} = 25 \text{ min}$$

Distance-velocity lag of 10 min

$$TR = 133 \text{ per cent}$$

$$t_f = 5500 \frac{\text{Min}}{\text{Per cent}} \qquad \frac{t_f}{TR} = 42 \text{ min}$$

We believe the settings mentioned will give a somewhat smaller initial deviation and shorter period of oscillation than the values used by the author.

Concerning second-derivative response, we agree with the author's comment that it is a very useful type. It is being used very successfully on long-time-lag applications, such as rayon shredders, tube stills, juice heaters, fractionating columns, and in various air-conditioning processes. The author does not indicate the second-derivative setting used in obtaining Fig. 13(c), nor does he indicate what units he would use to measure it. We would suggest the term "pre-act time," PA, which we have found useful. If V is expressed in watts, θ in per cent of range, and t in minutes, the equation for $-\frac{dV}{dt}$ in the paper may be written

$$-\frac{dV}{dt} = \frac{660 - 40}{t_f}\theta + \frac{660 - 40}{TR}\frac{d\theta}{dt} + \frac{660 - 40}{TR} PA \frac{d^2\theta}{dt^2}$$

Our method indicates that PA should have a value near 1.1 min with the other settings as noted for the application of Fig. 13(c). This means the coefficient of the second derivative should be

$$C = 28 \frac{\text{Watts}}{\text{Per cent/Min}}$$

It would be interesting if the author would compare this with the value of C or PA used in Fig. 13(c). For the examples with distance-velocity lags, we would suggest the pre-act times of 3.6 min and 6.1 min. With TR and t_f values as suggested, the settings for good control are thus completely specified.

G. A. Philbrick.[11] This paper is a worthy contribution to the literature and a fitting continuation of the Bristol and Peters paper[3] given a few years ago. Models of controlled systems are exceedingly useful in the study and application of automatic control; and the disclosure in this paper of a carefully worked out experimental equipment should help to make such methods better known. Just as pilot plants aid in the construction and operation of full-scale processing equipment, so model systems offer a means for developing the specialized technique necessary for the successful adjustment of controllers.

While the author has described a model system principally thermal, it is true, as he states, that "the fundamentals of control are much the same regardless of the particular controlled variable involved." Thus, although transfer lag, for example, is defined by him in terms of thermal concepts, it is a property as well of other kinds of system (e.g., chemical), although in general it is perhaps not as prevalent nor as pernicious as in many thermal systems. With artificially constructed systems, of course, such lags may be introduced at will to simulate control-resisting properties; this may be done whether such (model) systems are thermal, hydraulic, pneumatic, or electrical. For instance, a two-capacitor ther-

[11] The Foxboro Company, Foxboro, Mass. Jun. Mem. A.S.M.E.

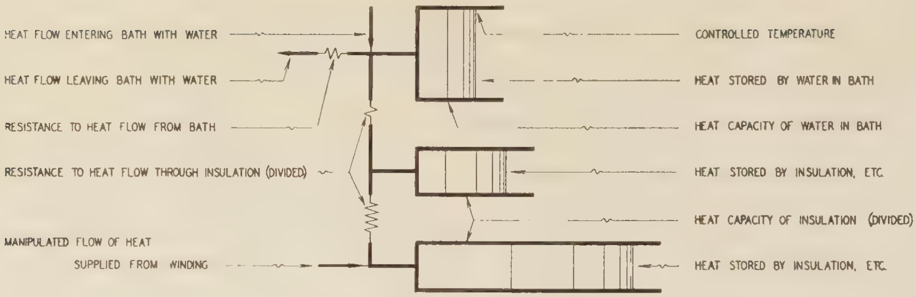

Fig. 14 Liquid-Level Model of Author's Thermal System

mal model was shown by Mason,[12] together with its hydraulic analog, in which transfer lag is the result of lumped, or concentrated, elements rather than of distributed elements as in the case of the thermal model described in this paper.

Since the subject matter of the present paper is coextensive in part with that of two earlier papers,[13, 14] by C. E. Mason and the present writer, it might not be out of place to point out some correspondences in nomenclature between the two presentations. "Throttling range" (Peters) and "proportional band" (Mason and Philbrick) are names for the same thing, the former expressed in percentage of the instrument scale, and the latter in actual units of the controlled variable. "Floating time" (Peters) is a derived expression and is the ratio of the "throttling range" (Peters) to the "reset constant" (Mason and Philbrick), the latter being referred to as "floating speed" by the author.

The collection of experimental curves included in the paper shows quite well the effect of controller adjustments following suddenly applied upsets of the two types chosen. For the proportional-plus-floating controller, a norm is chosen for both throttling range and floating speed adjustments, and the effect is indicated of changes in either adjustment from this norm, although not of changes in both adjustments together. This would require a complete square array, which would show in one corner, for example, the response obtainable with a large throttling range and a slow floating adjustment—the adjustments for averaging control.[14] Nevertheless, the author's results are unusually complete.

The experimental results, showing response in the presence of distance-velocity lag (or dead time) in the controlled system form a much-needed addition to the literature, especially since these results are compared with results for the same system, but from which such lag is absent. The method used by the author for simulating this kind of lag, and which was also used,[15, 16] in the analytical work of Callender, Hartree, Porter, and Stevenson, naturally may be followed in models other than thermal.

On the whole, the results presented corroborate the contention that model systems offer feasible representation of systems to which controllers must be applied in industry. The adequacy of the use of models, having lumped elements, is also upheld by the evidence now available. Theoretical results alone are poor comfort indeed without experimental support. In connection with the use of models and with the ability generally of one system to represent another, the writer would like to exhibit a simple liquid-level model, made of resistances and tanks, which has practically the same characteristics as the thermal system of the paper. Fig. 14 of this discussion is a diagram of such a system, with the analogies indicated in detail. Heat energy becomes quantity of liquid, and temperature becomes level. The relative sizes of the resistances and the capacitances (tank areas), corresponding to thermal resistances and capacitances, are indicated in Fig. 14. A wealth of confirming data[17] show that the reactions of hydraulic systems, such as this one, can be successfully computed from their known constants. This model is analytically simple, and it may readily be shown to react to flow changes in a manner indistinguishable from that shown in the paper for the thermal model. Automatic control, when applied to this system, yields response curves uncannily similar to those shown by the author.

E. S. Smith.[18] The empirical approach of this paper is both sound and sensible. It challenges mathematicians to produce commensurate results, especially where two-position control or transportation lag, i.e., distance-velocity lag exists.

A better comparison would be obtained by taking the actual temperature instead of that recorded, since the latter has excessive lag. In the paper, much of the control lag was due to the response lag of the measuring which governed the controlling. It is desirable that the measurement used as a basis of the comparison should have considerably less response lag.

It is requested that the closure include basic diagrams of controllers used, which were stated to give proportional-and-floating and second-derivative control, respectively. Objection is made to the terminology of the paper, which probably will cause confusion by taking valve velocity instead of position, since "proportional" is generally accepted to mean that the valve position corresponds with departure. It is requested that the final equation be placed upon the integral basis. Its correctness is questioned, hence, the request for the basic diagrams.

It may be noted that the paper agrees with the unpublished discussion by P. D. Keppler of the Lowe-Smith paper,[19] emphasizing the usefulness of higher derivatives with hard-to-control systems, such as have transportation lag.

This discussion is not to be taken as in any way minimizing the value of the paper in helping the workers in the theory of the art of controlling to keep one foot on the ground.

[17] Pneumatic and hydraulic versions of such model systems have been used for a number of years by the writer's company for purposes of instruction.

[19] "Reset Controller for Sump Pumps," by R. P. Lowe and E. S. Smith, *Power Plant Engineering*, May, 1941, pp. 79–80.

Author's Closure

The predictions of Messrs. Ziegler and Nichols check the experimental results closely enough to indicate that their methods have considerable promise. The author is glad to give additional power values, which they suggest as desirable for purposes of comparison. These will be found at the end of this closure.

While we have not made tests with the particular TR and t_f settings, suggested for use under the conditions applying to Fig. 12(b) and (c), it is evident from these curves, and from others obtained with different controller settings, that the suggested values would not give results as good as those shown. Decreased TR would increase the amplitude of oscillations following a disturbance, and an accompanying increase in floating time would increase the time required for these oscillations to center about that temperature corresponding to the control point. The maximum deviation cannot be reduced appreciably, because, in each case, the temperature has practically stabilized by self-regulation before control actions begin. Possibly this is the reason that the Ziegler and Nichols method of predicting settings does not seem to apply as well to these as to other conditions.

When the controller equation is considered in the form given in the Ziegler and Nichols discussion, the constants for the curves of Fig. 13(a) and (c) are approximately as follows:

	t_f	TR	PA
Fig. 13(a)	260	35	0
Fig. 13(c)	140	27	0.9

In this case, t_f and TR are in the same units as given in the paper. Term PA is in minutes. As applying to Fig. 13(c), t_f and TR are actual effective values and not merely those which applied before the second-derivative action was introduced. In explanation of this, the equation of the particular mechanism employed may be written in the form

$$-\frac{dv}{dt} = \frac{k_2}{1 - k_1\, k_3}\left[k_1\, \theta + (1 + k_1 k_3)\frac{d\theta}{dt} + k_3\frac{d^2\theta}{dt^2}\right]$$

The adjustments for floating speed, proportional-control action, and second-derivative action, affect constants k_1, k_2, and k_3, respectively. It will be noted that when $k_3 = 0$ (no second-derivative action), the constants k_1 and k_2 represent the usual adjustments for proportional-and-floating control. An adjustment of k_1 then changes the floating speed only, while a change in k_2 changes both proportional and floating components by the same percentage.

The adjustment of k_3 for second-derivative action is seen to modify the coefficients for floating-and-proportional control as well. It may be worth noting here that in practice this relationship is found to be favorable as compared with one which affects the second-derivative action only.

Referring now to the settings listed for Fig. 13(c), the value of 0.9 for PA is reasonably close to that of 1.1 calculated by Ziegler and Nichols.

The author appreciates the remarks of Mr. Philbrick who, with Mr. C. E. Mason, has carried out a considerable amount of interesting analytical work, based on hydraulic analogies. When combinations can be found in which response characteristics are similar, the particular device used is often relatively unimportant. Since the author's company has a particular interest in temperature control, it has seemed preferable to set up a "dummy" process on this basis. When testing particular temperature-control mechanisms, it is desirable, not only that the response characteristics be similar, but that the actual rates of response be approximately those found in industry. It is considered somewhat easier to obtain corresponding time lags in a thermal laboratory system than would be the case if time constants of hydraulic or electric systems were involved.

If we were dealing with an actual industrial process, it would be important to know the actual temperature as suggested by Mr. Smith. However, when we are using a laboratory process for the sole purpose of studying automatic control, nothing is lost by considering the measured temperature as the actual temperature and the lag of the primary element as part of the process lag.

The equation, given in connection with comments on the Ziegler and Nichols discussion, shows clearly how three control adjustments affected the proportional, floating, and second-derivative modes. The equation is based on the particular type of pneumatic controller used. Whether it is preferable to write this and similar equations with respect to the actual magnitude of the power at any instant, or the rate at which the power is varied by the operation of the controller, is a matter of personal preference. The author finds it simpler, as given, in the last-mentioned form. Those who find the other form easier to understand can readily obtain it by integration.

The following table gives additional information for the use of those who may wish to compare their own results with those of the paper. Figure numbers apply to figures of the paper.

Burning Pulverized Anthracite in Steam Power Plants

By C. H. FRICK,[1] ALLENTOWN, PA.

After citing early installations for burning pulverized anthracite in steam power plants, the author describes in some detail the present Pine Grove installation of the Pennsylvania Power & Light Company. This plant incorporates three boilers using pulverized anthracite exclusively, each boiler having a capacity of 180,000 lb of steam per hour. They have been operating successfully since 1927. A proposed two-boiler pulverized-fired installation at the Hauto plant of the company is also described. Each boiler, which is now on order, will be capable of producing 365,000 lb of steam per hour at 1325 psi and 930 F total temperature. Economic considerations entering into the decision to use this type of fuel are also considered in the paper.

The Pennsylvania Power & Light Company is the largest single user of anthracite. In order for the system to supply the gas, electric, and steam-heat service required, 27,000 tons of large sizes, 594,000 tons of No. 3 buckwheat, 753,000 tons of No. 4 buckwheat, and 146,000 tons of yet smaller sizes are burned, making a total of 1,520,000 tons per year.

There are now 108 anthracite-fired boilers in the company's power plants, varying in size from approximately 4000 to 18,000 sq ft of heating surface. Two just recently put into service are capable of producing 185,000 lb of steam per hr. These, however, are stoker-fired, and thus far are the largest anthracite-burning boilers ever installed.

At present, three of the larger boilers are fired by pulverized anthracite, while two larger boilers now on order will also be similarly fired. These will operate at about 1325 psi pressure with 930 F total steam temperature. Each boiler will be capable of producing 365,000 lb of steam per hr.

On the basis of the existing installation experience was secured which governed the decision again to use pulverized fuel.

History of Burning Pulverized Anthracite

The first experimental boiler plant to burn pulverized anthracite was a small two-boiler installation, made in 1918 by a coal company. This plant was abandoned in 1928, after sufficient proof was established that low-volatile fuel could be burned in pulverized form in a properly designed furnace. In 1920 and 1921, the same coal company erected a larger plant containing twelve pulverized-fired boilers of 500 and 600 hp, which plant is still in operation. It was one of the first power plants[2] designed to utilize anthracite slush, which at that time constituted all sizes below No. 3 buckwheat, previously considered waste incidental to anthracite mining.

This plant produces steam and electricity for direct use in the coal mines. The coal used is comparatively soft and therefore easy to grind.

Early Research on Coals. Tests conducted at this coal company's plant in 1924 on coals from nine different sections of the anthracite field, on a screen-type ball-and-pusher mill, indicated that there is a rather wide variation in the grindability of the coal from the various fields. The results of these tests are shown in Fig. 1, with mill capacity and power per ton, expressed in percentage of that obtained with coal from the extreme western end of the anthracite region, plotted against distance. The chart is plotted in this manner, since quantitatively these data are of little value today, because of improvement in the design of equipment. Relatively, they would hold true with the original type of milling equipment. However, with the ball-and-tube type of mill there is practically no difference because of coal characteristics. This is substantiated by the dotted lines in Fig. 1, showing results of tests at Pine Grove on a ball-and-tube type of mill with coal from three sources plotted relatively against the coal nearest Pine Grove. These tests were of a month's duration, and indicate very little decrease in performance with variable coal hardness.

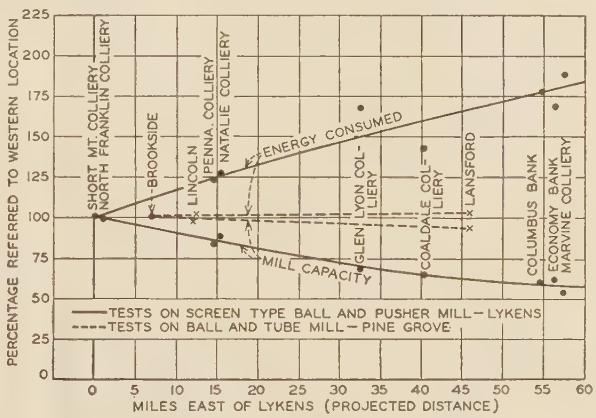

Fig. 1 Results of Tests on Grindability of Anthracite Coal From Various Fields

The first-mentioned coals were burned under an Edgemoor four-pass boiler having 5116 sq ft of heating surface and 680 sq ft of superheating surface. The furnace walls, of solid firebrick construction, contained a number of small ports for admission of secondary air. A suspended arch was used as a roof over the section of the furnace through which the coal was admitted. A stream of mine water, flowing continuously through a trough in the bottom of the boiler furnace, constituted the method of ash removal. Fig. 2 shows a sectional elevation.

Although these early installations and tests showed the practicability of using anthracite in pulverized form, no large installation was made until the Pennsylvania Power & Light Company, as a result of these investigations in the coal company's plant, decided to extend its Pine Grove plant by adding three large

pulverized-coal-fired boilers, which were put into service early in the year 1927.

PRESENT PINE GROVE INSTALLATION

Preparation Plant

Handling and Drying. Incoming coal is taken by skip hoists and conveyers to an elevated raw-coal storage bunker of 1000 tons capacity. From this bunker by means of conveyers, the coal is taken to two single-shell indirect rotary driers of 23 tons per hr capacity each.

These driers are 7 ft 6 in. diam by 45 ft long, driven by motors through pinion and circumferential gears. Each drier rotates in a furnace equipped with stationary grates on which No. 3 buckwheat is hand-fired. The gas travel is counterflow to that of the coal. The raw coal is reduced from its original normal moisture content of 12 to 14 per cent (winter weather, up to 20 per cent) to 1 per cent.

Gas from each drier passes through a cyclone for removal of solids, thence through a washer for additional removal of solids, and is finally discharged to the boiler stack.

After drying, the coal is elevated and transported to the mill bins, each of 22 tons capacity.

Grinding Equipment. The original milling equipment consisted of four 70-in. screen-type mills, each driven by a 350-hp motor. These, except for gear drives, were larger units, identical in type to the 42-in. mills in the coal company's plant previously referred to.

Later, one of these mills was converted to an air-swept type, which depended on recirculation of the product for control of fineness. It partially overcame one of the inherent deficiencies of the screen-type mills, in which there was no continuous control of fineness.

Eventually, two of the original screen mills were removed and two horizontal air-swept ball-and-tube mills were installed. These are 8 ft in diam by 17 ft long, and normally supply the entire pulverized-fuel requirements.

Pulverized coal, transported by air through these mills, is collected in cyclones from which it is pumped through pipe lines, using air as the transport medium, to bins of 120 tons capacity at each boiler. From these it is fed by mechanical feeders to the boiler burners.

All the vents from the various bins, cyclones, etc. are connected to a common venthouse, used as a settling chamber for the coal dust, from which the vented air with a small amount of entrained coal is taken to the suction of the primary-air fans, so that no coal is lost to the atmosphere. No bag filters or other equipment of such nature are used in this plant.

Boiler Plant. Each of the three pulverized-fired boilers is of the single cross-drum type, having about 17,700 sq ft of heating surface proper. Protection to the rear-wall refractories is afforded by a waterwall, connected into the boiler-water circulation. Originally, no cooling surface was planned for the bottom of the furnace, except that the first boiler had a water screen, located several feet above the bottom. For reasons which will be explained, new water-cooled-furnace bottoms were installed, consisting of tubes at an angle of approximately 45 deg, which are covered with cast-iron blocks, also connected into the boiler-water circulation. Fig. 3 shows a sectional elevation of these boilers.

Each boiler is equipped with an air preheater, which raises the temperature of the secondary air from room temperature to approximately 550 F. This secondary air is about 80 per cent of the total requirement. The boiler side walls are hollow, and the front walls have staggered airports. The secondary air passes through the hollow side walls to keep down refractory temperatures and is discharged through the ports in the front walls to complete combustion of the coal.

The coal is fired vertically downward, so that the heat of combustion travels up to ignite additional coal coming into the furnace. This is the only way anthracite can be fired.

The ignition temperature for pulverized anthracite is about 300 F higher than for bituminous, therefore, it is not possible to be as liberal in the use of waterwall cooling with the former as with the latter.

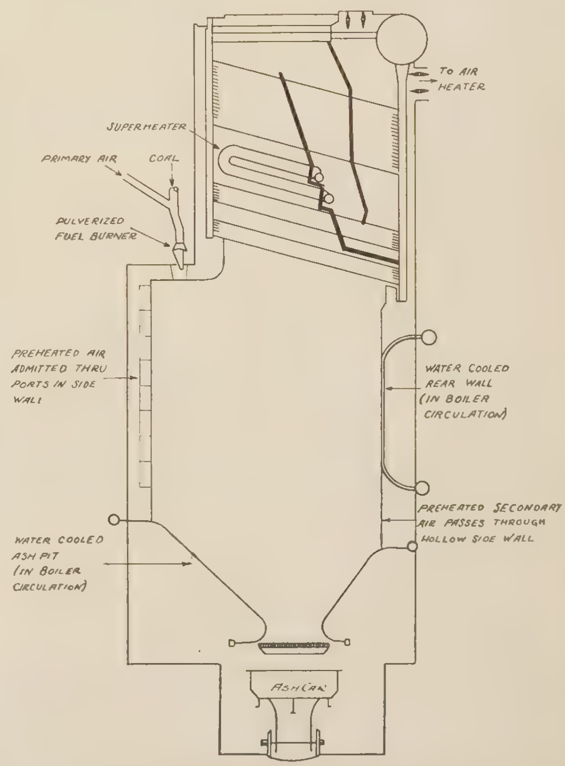

Fig. 3 Sectional Elevation of Pulverized-Anthracite Boilers at Pine Grove Plant

Operating Experiences

Preparation Plant. Shortly after being put into operation, it was evident that the maintenance of mills would be high and the capacity low. That the various mill changes made have produced improved results is evidenced by the statistics given in Table 1.

TABLE 1 PINE GROVE ANNUAL PREPARATION-PLANT DATA

	Preparation plant				
				Maintenance, cents per net ton pulverized	
Year	Size, per cent through 200-mesh screen	Pulverized coal per mill-hour, net tons	Kwhr per net ton pulverized	Mills	Total

[a] First ball-and-tube mill in service.
[b] Second ball-and-tube mill in service.
[c] Low, due to credit for material returned to stock.

Generally, since 1934, all preparation-plant equipment has given satisfactory service at low cost. Certain limitations are imposed, such as keeping moisture of the pulverized fuel to 1 per cent or less, to prevent arching in bins.

Except for higher grinding costs and energy consumption, as is to be expected, there is no marked difference between preparation of anthracite as compared with bituminous. However, the former has one distinct advantage, i.e., there are no explosion hazards, principally because of the low volatile content.

Driers. The driers as originally designed did not retain the coal long enough, nor was there sufficient mixing of coal and air to produce thorough and economical drying. The installation of additional cascading angles and retarding baffles improved the condition materially.

To insure thorough drying under all initial moisture conditions, it was found necessary to maintain the exit coal temperature at about 300 F, with a drier exit gas temperature of about 225 F. These temperatures are considerably higher than allowable in drying bituminous coal, which under similar temperatures would lose part of its volatile matter.

These improvements resulted in drying to 1 per cent moisture or less, as compared to only about 50 per cent initial-moisture extraction originally.

Boilers. The boiler furnaces, having a volume of 16,900 cu ft, were originally designed for a maximum heat release of 16,000 Btu per cu ft per hr. This was conservative, in order that capacity could be maintained with high-ash coal, at little sacrifice in boiler efficiency. Various tests conducted from time to time have shown this to be true.

Trouble was experienced when the first boiler went into service from ash which stuck to the bottom of the furnace (fusion temperature about 2450 F). It required from two to five hours daily to loosen up and remove the ash from the floor, so that it could be dumped through the gates. It was necessary to operate with a higher percentage of excess air in order to prevent excessive temperatures, which would cause slagging of the entire screen and necessitate taking the boiler out of service for cleaning.

This condition could be alleviated by reducing the flame length well above the hearth screen. However, by so doing, the decreased flame travel produced excessive carbon losses in the stack gases, and transferred the slagging trouble to the boiler tubes themselves.

This experience immediately warranted a change in the design of the remaining two boilers to include Bailey furnace bottoms. Their successful performance later justified a similar installation in the first boiler.

After a period of test with varying air distribution through the front wall ports, operation became very well stabilized so that ash removal was simply a matter of opening the ash gates periodically. Boiler-tube slagging is effectively reduced by soot blowers in the first pass, so that continuous service periods of from two to three months are not exceptional for these boilers.

The operating data in Table 2 indicate the consistent, dependable, and economical performance obtained at this plant with pulverized anthracite.

TABLE 2 OPERATING DATA OF BOILERS AT PINE GROVE PLANT

Year	Boiler load factor,[a] per cent	Boiler availability, per cent	Per cent of ash in coal, dry basis	Over-all boiler efficiency, per cent	Dry flue-gas loss, per cent	Combustible in refuse loss,[b] per cent
1931	287	82.9	15.4	75.1	6.1	9.0
1932	276	88.0	14.0	77.2	7.2	5.4
1933	264	87.6	14.1	78.2	8.8	4.5
1934	279	85.9	14.3	80.5	8.6	4.8
1935	278	92.9	13.5	82.0	8.2	4.7
1936	284	92.5	13.2	83.2	8.0	4.2
1937	280	92.8	14.7	83.8	7.8	5.3
1938	273	89.6	14.8	81.5	7.9	5.8
1939	282	91.9	14.9	81.8	7.6	5.6
1940	282	91.0	15.0	80.8	7.8	5.2

[a] Boiler load factor as used here is intended to express the average monthly rating referred to 100 per cent rating as a base, and not the percentage of maximum capacity.
[b] Includes refuse up stack.

The present practice is to maintain a coal fineness of about 77 per cent through a 200-mesh screen, which has been found to be most economical for this particular installation. Successful operating results are secured by limiting the variation in fineness to a narrow range, and this is accomplished by having the operators take hourly samples of pulverized fuel, screen them immediately, and make mill-draft adjustments if necessary.

The total preparation-plant power requirement is about 3 per cent of the main unit capacity supplied. Because this plant incorporates a storage system, the preparation plant is shut down during peak-load hours.

Boilers are started from the cold state by means of several torches, which burn either kerosene or light oil, and which are inserted through the front walls of the furnace. They are left burning only long enough to ignite the coal which is turned on gradually from the overhead burners. Invariably, the torches are removed before the boiler is up to pressure. Once ignition is secured, maintaining it from about 90,000 lb of steam per hr to 180,000 lb per hr is possible without using torches.

New Developments at Hauto

As previously mentioned, the company has recently contracted for the two largest boilers ever designed to burn anthracite in any form. These will also be pulverized-coal-fired. After considerable study of the relative merits of the unit system versus the bin or storage system, it was decided to use a storage system similar to that at Pine Grove. The advantages in favor of extending the use of the bin system to this plant are as follows:

1 Capacity will be gained by shutting down the preparation plant over station-peak hours. This will amount to 1300 kw or about 4 per cent of the topping-unit capacity for which these boilers will supply steam.

2 One shift of preparation-plant labor will be saved.

3 Any failure of preparation-plant apparatus will not immediately affect the boiler output, because of the prepared fuel in storage bins which have a capacity of 240 tons, sufficient for 12 hr at maximum conditions.

4 Better control of product, since milling conditions can be set independently of boiler requirements for continuous maximum capacity consistent with fineness desired. This will reduce the energy requirements, as compared with the unit system, since there is only a variation of about 10 per cent in energy requirements between full load and no load, because the amount of coal in the mill is only a small percentage of the ball charge.

Reasonable evaluation of these advantages has justified the slightly higher cost of the bin over the unit system in this case. This is directly contrary to the usual practice when using bituminous coal, for the principal reason that almost double the milling capacity is required for anthracite than for soft coal, for equivalent initial moisture. However, with as much as 20 per cent moisture, which prevails in winter, this ratio probably would be 4 times as great, making the capacity value of the preparation plant an appreciable figure. There will be three mills with a total capacity of 57 tons per hr. The two boilers will be capable of burning a total of 40 tons per hr.

As at the Pine Grove plant referred to previously, the burners will project the coal vertically downward through a short horizontal arch. The point of entrance will be about one third of the distance between the top and bottom of the furnace.

The entire air supply for combustion will be preheated to a temperature of approximately 590 F at full boiler load. A portion of this preheated air, ranging from 5 to 10 per cent will be mixed with the coal streams through seven feeders, each one supplying two burners. Supplementary primary-air fans will act as boosters to maintain adequate air pressure at the burners.

Surrounding the coal burners will be tertiary-air nozzles, which will supply air amounting to anywhere from zero to approximately 40 per cent of the total air for combustion, as found necessary. The balance of the air will be injected through a series of ports in the front wall of the furnaces served by three horizontal ducts. This air, known as secondary air, will vary anywhere from 60 to 95 per cent of the total, as found necessary. Individual control dampers will be installed on the primary-air supply of each boiler, on each individual tertiary-air supply, and

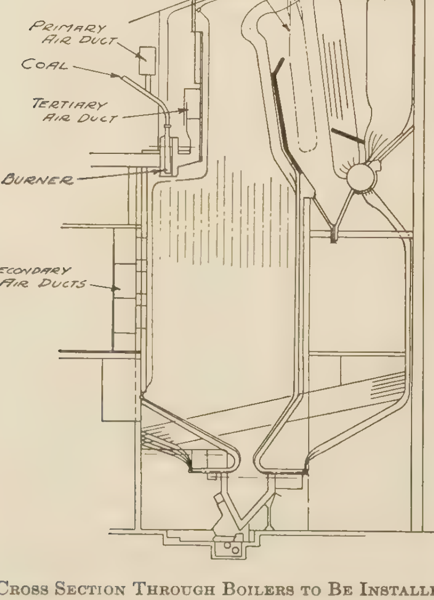

Fig. 4 Cross Section Through Boilers to Be Installed at the Hauto Plant

also on each duct of the secondary-air supply. The entire installation will be automatically controlled, using inlet-vane dampers on the forced-draft and the induced-draft fans, the actuating medium being primarily steam pressure.

Because of the size of the boilers, two forced-draft fans for each boiler have been specified to deliver the air through a common regeneration rotary-type air preheater. There will also be two induced-draft fans, so that, in case of trouble with either one, the remaining unit will enable about 60 per cent of the boiler output to be maintained.

The raw-fuel supply is expected to contain approximately 14 to 16 per cent ash (dry basis) and will be of such size that all particles will pass through a $^3/_{32}$-in. round mesh screen. The guaranteed boiler efficiency at full load is 81.5 per cent, with coal pulverized to 85 per cent through a 200-mesh screen. This sizing was specified to insure ample reserve milling capacity.

The furnace volume will be 25,000 cu ft, with an anticipated heat release of 20,000 Btu per cu ft of furnace volume per hr. The entire furnace bottom will have fin-type tubes. Fig. 4 shows a cross section of these boilers.

General Considerations for Use of Pulverized Anthracite

In general, the raw coal, used in a pulverized-anthracite installation, is smaller in size than it is practical to burn on stokers, and is usually the size remaining after all such usable stoker sizes have been removed from the raw material. There are millions of tons in banks in the anthracite territory, with additional tonnage being currently produced.

The moisture content of small anthracite is usually high, running from 8 to 15 per cent, or even more in some cases. This is particularly true of railroad-car deliveries during the cold-weather months, when coal is frozen. This condition is due to the large amount of water used in its preparation. The smaller the size of the coal, the more moisture it will inherently retain. Very small sizes of anthracite seem to act very much like a sponge, holding a considerable percentage of moisture. Samples of this kind of coal taken on the very hottest summer day will indicate as much as 8 to 10 per cent moisture at a distance of 2 to 3 ft below the surface of the pile. This even applies to coal which has been in storage for a very long time.

This high moisture content presents a handling problem in winter, necessitating a coal-thawing shed, since such coal frozen in railroad cars would entail an unloading cost of from 15 to 20 cents per ton, whereas, with proper thawing facilities it can be unloaded for about 25 per cent of this cost.

From an over-all standpoint, the economic use of such fuel is limited to the anthracite-producing centers or territory adjacent thereto, where large piles of these small sizes are within low-cost-transportation zones.

This can be readily understood by comparison of the figures in Table 3.

TABLE 3 RELATIVE DELIVERY COSTS OF VARIOUS COALS

Kind of fuel	Size	Method of burning	Ratio of cost per million Btu, to lowest-cost fuel: Delivered to plant	Delivered to boilers
1 For Low Freight Zones Within Anthracite Territory				
Anthracite	Slush or culm	Pulverized	1.00	1.00
Anthracite	No. 4 buckwheat	Stokers	1.30	1.04
Anthracite	No. 3 buckwheat	Stokers	1.80	1.36
Bituminous	Stoker	Stokers	3.20	2.50
2 For Freight Zones Immediately Outside of Anthracite Territory				
Anthracite	Culm	Pulverized	1.00	1.00
Anthracite	No. 4 buckwheat	Stokers	1.17	1.02
Anthracite	No. 3 buckwheat	Stokers	1.47	1.23
Bituminous	Stoker	Stokers	1.96	1.63
3 For Freight Zones Within Next Cheapest Bituminous Freight Zone				
Anthracite	Culm	Pulverized	1.00	1.00
Anthracite	No. 4 buckwheat	Stokers	1.12	1.02
Anthracite	No. 3 buckwheat	Stokers	1.35	1.18
Bituminous	Stoker	Stokers	1.41	1.24

All small sizes of anthracite take the same freight rate from a given source to a certain location within the anthracite territory. In section 1 of Table 3, the cost for the cheapest usable stoker fuel per million Btu at the boilers, on an as-received basis, is about 4 per cent higher than with fuel for pulverizing. To import bituminous coal would cost approximately 150 per cent more for the same steam costs, assuming equal boiler economies in all cases.

In the case of section 2, Table 3, by going immediately outside of the anthracite territory, say Allentown or Easton, we are confronted with an increased anthracite freight rate, with no change in bituminous rate, thereby decreasing the bituminous cost differential; and the next step, section 3, for further increased anthracite rate and lowered bituminous rate, cuts the original difference in half. This comparison is made on the basis of present mine prices and, as will be noted, the greatest favorable differential for pulverized-anthracite slush or culm occurs nearest the source.

Since the "cost per million Btu delivered to boilers" column includes the cost of pulverization for this fuel, the question can be raised whether the 4 per cent decrease in favor of utilizing this fuel warrants the increased investment required over a stoker plant for the cheapest stoker fuel listed. There are several reasons for giving preference to pulverized fuel, as follows:

1 The availability of No. 4 buckwheat is limited, dependent largely upon current mine production.

2 There is only about an 8 per cent investment differential in favor of stokers, for such an installation as is being considered, because with pulverized-firing only two boilers are contemplated, whereas, with stoker-firing, using the largest stokers obtainable for small anthracite, four boiler units would be necessary.

3 The final answer is that pulverization makes usable in the territory a natural resource which would otherwise be wasted, and heretofore not usable by any other means, at a total cost very close to that obtainable with marketable sizes of limited quantity.

Every case is a special problem, requiring consideration of all factors involved, before final selection of type of fuel and equipment can be made.

Discussion

J. R. Baker.[3] The Holtwood steam-electric plant of the Pennsylvania Water & Power Company, consisting of three cross-drum boilers, each having 14,831 sq ft of heating surface, and equipped for burning coal in pulverized form, was placed in operation in 1925, with the expectation that anthracite coal, obtained from river-bottom deposits in the pool behind the Holtwood dam on the Susquehanna River, would become the principal fuel. Initially, dredging capacity was insufficient to supply the entire fuel requirements, and the available river-bottom anthracite was burned as a mixture with the necessary bituminous coal. Since 1931, almost all boiler coal has been river anthracite. At times during the early years, bituminous coal formed the entire fuel supply, so that opportunity has been had, with the equipment installed, to note the performance of the boiler plant with fuels of composition varying from 100 per cent bituminous to 100 per cent anthracite. The following will therefore supplement the author's data by a comparison of boiler-plant operation with the two different fuels.

[3] Baltimore, Md. Mem. A.S.M.E.

The plan dimensions of the Holtwood furnaces below the horizontal firing arch are 17 ft wide by 23 ft from front to rear wall. Coal is fed vertically to the furnace through eight fantail burners, with axes parallel to side walls, placed in a horizontal arch near the top of the furnace. The arch extends about 9 ft from the front wall, thus reducing the front-to-back dimension of the upper portion of the furnace to 14 ft. The depth of the furnace under the firing arch to the water-screen tubes over the ashpit is 25 ft; the height of furnace above the elevation of the arch to the boiler tubes averages 10 ft. The furnace volume above the water screen is about 11,500 cu ft. The average length of travel of the coal from the burners to the first boiler pass is about 50 to 55 ft. The first boiler pass is adjacent to the front wall of the furnace above the firing arch. The path of the burning coal is thus downward along the front wall, backward toward the rear wall, up along the rear wall, gradually crossing toward the front wall above the firing arch, forming almost a closed loop in the upper part of the furnace.

The side and front walls are air-cooled refractory walls, and the rear wall is a solid refractory wall with 4-in-OD waterwall tubes on $10^1/_2$-in. centers in front of it opposite the front wall under the firing arch. Similar tubes on similar spacing screen the ash-hopper slopes and floor which form the bottom of the furnace. The projected area of the rear wall and ash-hopper screen tubes and of the boiler above the furnace is equivalent to about 17 per cent of the area of refractory walls and projected area of the refractory ash hopper. For comparison, in the Pine Grove furnaces, the ratio of projected area of water-cooled surface to refractory area appears to be 40 per cent; the Hauto furnaces appear to be almost entirely water-cooled. It is apparent that the Holtwood furnaces can be classed as refractory furnaces.

The bulk of the air for combustion in the Holtwood furnaces is induced by furnace draft through horizontal air lanes in the side and front walls, the air entering the lanes at the rear of the side walls and flowing into corresponding lanes in the front wall, from which the air passes at relatively low temperature into the furnace through some 60 ports in the front wall. Some air is induced through the burner casings and some, estimated at from 10 to 15 per cent of the total, enters through the burners at about atmospheric temperature with the coal, at several inches of forced draft.

The average steaming rate of the Holtwood boilers is about 110,000 lb of steam per hr, equivalent to about 250 per cent of normal rating. At this load, the Btu in coal per hour entering the furnace per cu ft of furnace volume is about 12,900, equal to about 56,300 Btu per sq ft of furnace-wall area.

The furnaces were not conveniently operated continuously at ratings of 250 per cent and higher on bituminous coal because of the slagging of the furnace walls, the entrance of the first boiler pass, and in the ash hopper. Ash is removed from the ash hopper by hand hoes through three doors at the level of the ash-hopper floor. When the ash slags materially it is difficult to dislodge it from the slopes of the ash hopper because of the distances involved. When burning bituminous coals, there was the constant liability of hot spots on the walls with consequent washing of the refractories. With coals having ash of low fusing temperatures, frequent hand-lancing of the first boiler pass was necessary to prevent plugging.

These difficulties diminished as the proportion of river anthracite was increased. The ash-fusion temperature of the river anthracite is over 2700 F. There is no slagging problem with anthracite, although the corners and upper parts of the ash

hoppers must be cleaned by hand every few weeks by entering the ash hopper. Overheating of the furnace walls does not occur when burning anthracite, and the wear of the refractory walls results from gradual spalling with temperature changes rather than from active chemical deterioration by molten slag.

Probably the most noteworthy difference between the Holtwood furnaces and those described by the author is the use of preheated secondary combustion air under positive control in his furnaces. He mentions the higher ignition temperature of anthracite coal, but says nothing about the differences in volatile and fixed-carbon contents of the two coals. The high fixed-carbon content of anthracite causes it to be relatively slow-burning compared to bituminous, and this fact makes the mixing of the secondary air with the coal particles, as they move through the furnace, of the utmost importance. It was quickly found with the Holtwood furnaces that the distribution of admission of secondary air to the furnaces should be radically different with the two coals. When burning bituminous, better combustion results were obtained with most of the secondary air entering through the upper ports just below the burners, that is, the air was required near the point where the coal entered the furnace. This distribution is found to be almost impossible with anthracite, when most of the secondary air is admitted through the lower lanes; in fact, the upper air lanes are practically closed, except for some leakage. In the Holtwood furnaces, the problem of combustion is thus twofold, that is, to bring the coal to ignition temperature as quickly as possible and to promote mixing of the coal with the secondary air in a part of the furnace where the coal has lost its initial velocity energy. Such mixing must come from the slow-moving stream of induced secondary air.

The difference in ignition temperature between bituminous and anthracite of 300 F, mentioned by the author, would be neutralized to some extent by his secondary and tertiary combustion-air temperature of 550 to 590 F, but even if the anthracite coal would be brought quickly to the ignition temperature as it enters the furnace, the difference in burning characteristics still remains and presents the major problem of complete combustion of the fixed carbon before it leaves the furnace. The author states that the only way anthracite can be fired is vertically downward so that the heat of combustion travels up to ignite additional coal coming into the furnace. This, it is believed, can be amplified by pointing out that vertical firing with reverse flow of the furnace gases also gives the longest possible travel of the coal particles in the furnace, and that the scrubbing action of the oppositely moving streams of gases probably contributes to turbulence or mixing of the combustion air with the burning coal.

The cross sections of the Pine Grove and Hauto furnaces show that the coal travel in the later designed furnace is probably materially longer than in the first design of furnace. An exact comparison in this respect would be of interest. The Hauto furnace could be expected from the cross sections to give more turbulence than occurs in the Pine Grove furnace with resulting decrease in unburned combustible in the stack gases.

On the other hand, the Hauto furnace, Fig. 4 of the paper, indicates that all furnace walls as well as the ash hopper will be covered with fin tubes. If this is a correct interpretation of Fig. 4, it represents a distinct departure from the basis of design of the Holtwood and Pine Grove furnaces, both of which are largely refractory. It has been a moot question as to the relative amount of water-cooled surface which can be utilized when burning pulverized anthracite, and the Hauto design may provide an answer on this point.

Experience at Holtwood leads one to think that practically no slag would adhere to furnace waterwalls when burning river anthracite, certainly not to the extent reported in the case of some recently designed furnaces for burning bituminous coal. The walls should therefore remain cold in operation instead of approaching furnace temperature such as refractory walls do in service. However, since cold furnaces are lighted at Holtwood with the aid of only two small oil torches, continuously cold furnaces could tend to produce unburned combustible only in the relatively thin layer of gases along the wall surface. It seems reasonable to assume that the long gas travel in the Hauto furnace and its cross-sectional aspect will promote sufficient turbulence to keep the combustible loss to an acceptable amount. The performance of the Hauto furnace will be of interest in this regard.

Experience at Holtwood in drying and pulverizing river anthracite is quite similar to that reported by the author, and the data given by him for mill costs, boiler efficiencies, etc. are likewise applicable to Holtwood, after modification for the absence of air preheaters. His data indicate that the combustible loss in refuse is the next largest boiler loss after the dry-gas loss. It has been found at Holtwood that if the secondary-air admission is not properly adjusted, the combustible loss may equal the dry-gas loss. The fuel used in drying anthracite at Holtwood, preparatory to pulverizing, amounts to about 3 per cent of the boiler fuel. It is assumed that the author's data for over-all boiler efficiency includes this loss for drier fuel.

J. B. Cordiner, Jr.[4] What effect does a change in ash content have on the operation of pulverized anthracite in installations such as those described? In other words, if the ash content were suddenly changed from 11 per cent to 19 per cent, how would this affect ignition, output, and over-all efficiency?

It is admitted that the ash content should be as nearly constant as possible to insure best results. What keeps the ash content constant at the 14 to 15 per cent shown in the figures?

E. L. Willson.[5] The coal to which the author refers in his discussion of the economics of pulverized anthracite under various names of culm, silt, slush, etc. are by-product sizes which are produced necessarily as a result of the mining and preparation of anthracite in sizes intended for domestic use. There are several sizes smaller than those used generally for heating homes which have found a market in industrial use, so that the successful pulverization and combustion of coal which passes through $^3/_{32}$-in. round mesh screen appears to be the ultimate step in the utilization of the entire fuel value of anthracite.

Being a by-product of the preparation of coal for domestic use, the production of this fine size tends to become seasonal and is greater during the winter heating season when the problem of freezing in transit presents a serious unloading problem.

The necessity for the thawing shed, mentioned by the author as a means for reducing year-around unloading costs, is not necessary if ample ground storage is available close to the colliery. Reloading from a storage pile yields coal uniform in moisture and ash content, the latter approximating closely the calculated weighted average ash content of cars dumped into storage.

The selection of pulverized anthracite by the author's company for the important installation which he describes indicates that the technique of preparation and combustion of this fuel has been standardized. The prospect for increased utilization of anthracite fines minus $^3/_{32}$-in. mesh is therefore of interest to the anthracite-producing companies. However, if prospective users, in their desire to minimize investment cost, insist on the extreme minimum in ash content, they will find their sources of supply limited. Carrying the process of de-ashing beyond reasonable

[4] First Lieutenant, U.S.A., Office of the Chief of Engineers, Washington, D. C.

[5] Lehigh Navigation Coal Co., Philadelphia, Pa.

limits is accomplished at a great sacrifice in efficiency in the preparation process, a waste of good fuel values in the tailings, and costs increased beyond an economic return. An additional investment in mill capacity, sufficient to provide for the desired boiler output, using coal of ash content higher than the desired minimum, will be justified by a much larger source and greater reliability of supply.

Because of its high and uniform fixed-carbon ratio, anthracite lends itself to the premium-and-penalty basis of purchase contract, based on a uniform delivered cost per million Btu. The relation between Btu per pound and per cent of ash is a simple straight-line function from which can be developed a factor for adjusting a base price per ton of coal of an agreed base ash content to a price per ton above or below the base price for each 1 per cent of ash lower or greater than the base ash. Ash determination is a rapid and inexpensive test, which may be applied to individual cars by the shipper, and checked if desired by the purchaser.

Such contracts have been in force between some anthracite producers and their larger customers for nearly 10 years, and have proved satisfactory.

Author's Closure

For comparison with Mr. Baker's figures on Holtwood, the Btu in coal per hr entering the furnace per cu ft of furnace volume at Pine Grove is about 13,200, equal to about 56,000 Btu per sq ft of furnace-wall area at 282 per cent of normal rating.

In the case of the new Hauto boilers, the Btu input per cu ft of furnace volume will be about 20,000, equivalent to about 54,500 Btu per sq ft of wall area with a boiler output of 365,000 lb of steam per hr.

At Pine Grove most of the secondary air is also admitted though the lower lanes, and it is anticipated that similar practice will be followed at Hauto.

As a comparison to Mr. Baker's figure of 50 to 55 ft for the coal-travel distance in the Holtwood furnaces, at Pine Grove the comparable distance is about 50 ft and at Hauto it will be about 75 ft.

Not all of the furnace-wall area will be exposed. Initially about 20 per cent will be refractory-covered, subject to modification as experience indicates the necessity for changing after these boilers are in service.

The over-all boiler-efficiency figures given in Table 2 include drier fuel. This amounts to about 2.6 per cent of total fuel at Pine Grove; and for Hauto, it is estimated, it will run about 3 per cent.

Change in ash content, as indicated by Mr. Cordiner, would not have any appreciable effect on ignition; however, from tests conducted with coals of varying ash, boiler capacity varies inversely about 2.8 per cent for each per cent variation in ash for the same coal weight input. This, however, can usually be compensated for up to the limitations of the feeders, burners, etc., to handle the increased amount of coal required to maintain a fixed output.

Similarly with respect to boiler efficiency for anthracite within 12 to 20 per cent ash limits, there is an inverse variation of about 150 Btu per lb of dry coal for each per cent ash variation. Tests have indicated that the boiler heat absorption above feed varies inversely about 230 Btu for each per cent ash variation within these same limits. If, with a known coal of say 12,700 Btu per lb dry, corresponding to about 13.3 per cent ash, an absorption of 10,000 Btu per lb of dry coal is obtained in the boiler, the average over-all efficiency is 78.7 per cent. With an increase of 1 per cent ash in the coal, these relative quantities become 12,550 Btu per lb of dry coal and heat absorption of 9770 Btu per lb of dry coal, or an efficiency of 77.8 per cent, a decrease in efficiency of 0.9 point, or a 1.15 per cent decrease.

The ash content of the fuel delivered for the various years is nearly constant because coal companies are preparing coal to meet definite specifications. All coal is purchased on a bonus-and-penalty basis with a base price for coal having 14 to 16 per cent ash (dry basis). The uniformity in quality indicates the advantages of some such method.

Mr. Willson's statement relative to the necessity for a coal thawing shed is true if coal companies could deliver fuel uniformly to a power plant in winter months by loading from a storage pile. However, colliery production is higher as the weather gets colder, and consequently the quantity of smaller sizes of fuel also increases. This fuel when loaded wet in cars may be held in railroad yards for several days and arrives at the plant in a frozen condition, if shipped according to a definite delivery schedule; or if shipped as loaded, the plant unloading facilities are then taxed to a point where it must lay over in cars so that it freezes before it can be unloaded.

Automatic Burning Control in Rotary Kilns

By WILLIAM E. REASER,[1] EASTON, PA.

Significant developments in automatic regulation of the burning process in rotary cement kilns have occurred in the last decade, but general application of control devices has proceeded slowly. Indeed, neither the real import of the subject nor the extent of the progress is yet widely appreciated, though there are sufficient installations of various equipment to demonstrate the worth of a scientific approach to a problem which has been a typical rule-of-thumb operation. This paper discusses achievements in the field through reference to diagrams, charts, and illustrations in order to bring about a more universal understanding and to establish a background for additional thought which may encourage further experimentation. Moreover, although the discussion pertains especially to cement-clinker burning, the same basic principles of control are applicable to many other manufacturing processes employing rotary kilns.

THE bituminous-coal industry should be decidedly interested in the subject of automatic burning control in rotary kilns, because soft coal is the primary source of heat in cement mills. The latest complete figures available,[2] covering the fuel consumption of the cement industry for the year 1939, when 122,259,154 bbl of cement were finished, are as follows:

Bituminous coal, tons...........	5,227,756
Oil, bbl (42 gal).................	2,378,762
Gas, cu ft......................	40,233,089,789

Analysis of these figures shows that approximately 70 per cent of all heat units purchased by cement manufacturers come from bituminous coal. Naturally, as production rises, the total tonnage will increase. In 1941, it is expected that approximately 150,000,000 bbl will be finished, requiring nearly 6,500,000 tons of coal of which about 95 per cent is burned in the kiln process. The remaining 5 per cent is consumed in the preparation of raw materials and pulverized fuel. Because of the evident importance of coal, reference to control apparatus will emphasize its use, although the fundamental ideas involved can be utilized for oil- and gas-fired kilns equally well.

Manufacturers of cement, too, have good reason to show marked concern in the problem, since the burning operation is one of the most important and most expensive processes in the sequence of production. Especially when waste-heat steam generators are used, the kiln department is truly the very "heart" of the entire mill, because a continuous balance must be maintained between clinker output and power generation to secure maximum over-all economy. Since, on the average, a barrel of clinker requires about 100 lb of coal, fuel may represent from 15 to 25 per cent of the total manufacturing cost, a far more important item than in the average industrial enterprise. Refractory maintenance is a very essential consideration as temperatures of 2600 to 2800 F must be attained for heating the material. But above all, there is the problem of striving constantly for improved quality and greater uniformity of clinker, aims which cannot be accomplished to the highest degree through manual operation, even with the use of instruments to act as "seeing eyes."

Automatic-control apparatus is helping to meet these difficulties. Plant records show savings ranging from 5 to 10 per cent of the fuel expense alone and, in addition, considerably lengthened life of refractories due to elimination of extreme temperature fluctuations in the burning zone. Positive control of firing conditions is responsible for uniform rates of waste-heat steam generation, while, at the same time, it is improving quality and uniformity of product to the extent that new and more precise specifications can be satisfied. To hold maximum clinker temperatures within limits of ± 25 F and to maintain kiln speeds at uniform rates without stoppages for "heating up" are some of the restrictions recently imposed on producers. Such requirements demand the intelligent application of modern instruments and control.

Methods of Kiln Operation

In order to comprehend the problem, it must be understood first that there are two general methods of operating a rotary kiln:

1 Maintain a constant combustion rate, that is, supply fixed safe maximum quantities of air and fuel, and vary the speed of the kiln to produce the necessary temperature of material in the burning zone.

2 Maintain a fixed speed of kiln and vary the combustion rate, that is, modify the supply of air and fuel to procure desired burning temperatures.

Such procedures might well be considered "ideals," which, because of certain practical limitations, cannot always be followed. Nevertheless, they provide basically sound patterns from which necessary deviations are expected and permitted.

Various attempts have been made to regulate automatically the flow of material through the hot zone, and to insure combustion at maximum efficiency, the two principal points of control. In no kiln, however, have both of these elements been completely governed by co-ordinated auxiliaries, although in several instances semiautomatic control has been installed with gratifying success. A typical example of the latter approach is an achievement worthy of attention because it deals adequately with a fundamental consideration, draft control. The arrangement of kiln and regulating apparatus is illustrated schematically in Fig. 1.

In operation, the scheme aims to set a constant combustion rate and, thereafter, to produce desired clinker temperatures by varying the rate of flow of material through changes in kiln speed.

Pulverized coal is supplied to the kiln through a blast pipe which receives hot primary air from a rotary cooler. Secondary air also comes from this source. The weight of air entering the hood depends upon the magnitude of the induced draft at this point, if it be assumed the openings and clearances are fixed in size and air density is constant. With proper precautions, these assumptions can be realized. Thus, to set the combustion rate, a simple draft control developed for furnaces of steam generators is applied. A controller, operating with compressed air as the power medium, adjusts a damper in the stack to maintain a predetermined hood draft. A typical chart, Fig. 2, illustrates the fact that the system functions to hold the draft throughout the day at 0.065 ± 0.005 in. of water regardless of variation in

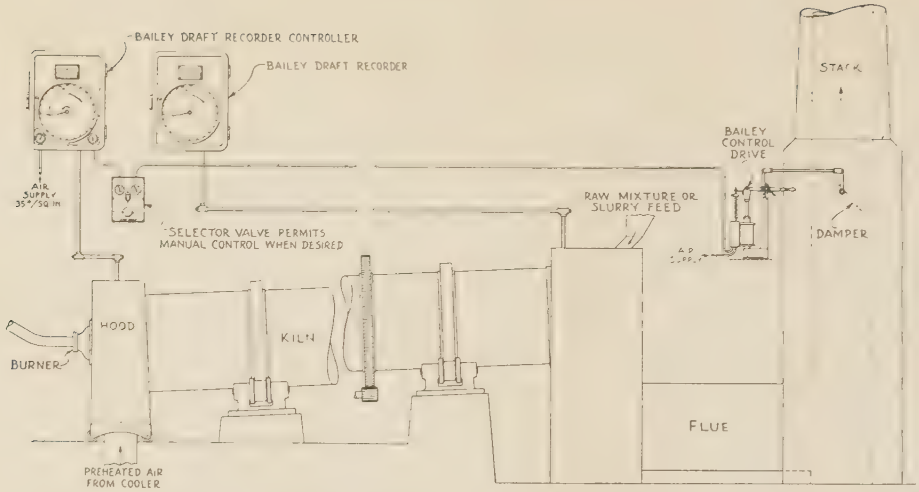

Fig. 1 Diagram of Hood-Draft Control System for Rotary Kiln in Which Secondary Air Is Supplied Under Induced Draft

draft loss through the kiln and gas passages. In addition to fixing the air supply, the effect of draft control is a definite aid in preventing undesirable movements of the position of the hot zone in the kiln.

Once the draft is set, primary air and fuel flow are selected to produce optimum combustion efficiency as determined by Orsat analyses of exit gases and consideration of the type of flame necessary to meet burning requirements. When the air-fuel ratio is fixed by the engineer in charge, the operator, commonly referred to as a "burner," is not permitted to adjust draft, primary air, or fuel, except in the event of an unusual circumstance, when temporary changes are in order. To complete the burning process, kiln speed is varied to maintain the necessary clinker conditions as shown by some temperature-measuring device, or simply by visual observation on the part of the burner.

Attention is directed to additional equipment considered essential. A feed-end-draft recorder is mounted in a convenient position alongside the instrument measuring hood draft, in order that the burner may observe at all times the draft loss across the kiln. An increase in draft loss generally indicates that a ring is forming (in rotary-kiln operation, a ring is a common term for the mass of material which occasionally builds up and restricts the opening in the kiln), and it is highly desirable to take immediate steps to eliminate the formation. One effort sometimes successful is to make an abrupt change in the draft, and this can be done readily by the means provided for manual adjustment of the damper. Such hand control is also useful when the fire is first lighted preliminary to starting production, and also when taking the kiln out of service.

Results from this mode of procedure are most satisfactory, yet certain limitations should be apparent. In attempting to establish a constant rate of heat release, a pulverized-coal feeder is set at some fixed speed which at the time delivers the correct quantity of fuel to produce desired combustion efficiency, as determined from an average of a number of gas samples. Unfortunately, even the best equipment does not continuously deliver an unvarying weight of fuel. However, experience has shown it to be possible to accomplish a setting of air-coal ratio which will be maintained within close practical limits from one day to the next. The general plant policy calls for a careful check on combustion conditions twice every 24 hr.

With regard to altering kiln speed to meet temperature specifications, certain authorities suggest that the action producing somewhat abrupt changes in velocity of material flowing down

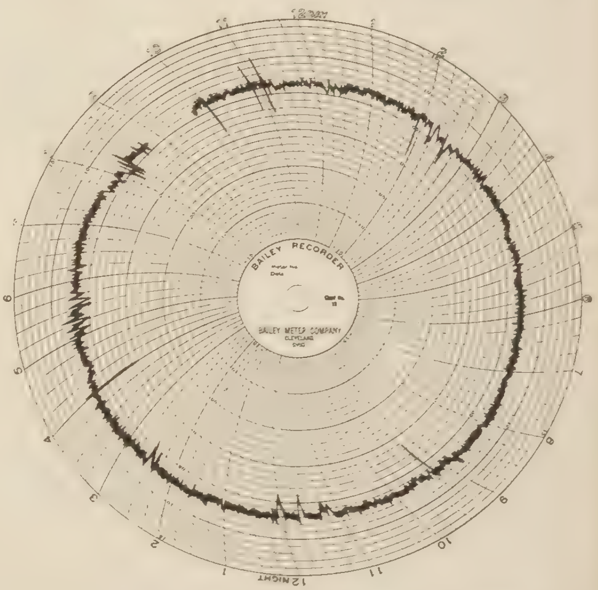

Fig. 2 Typical Chart Made by Recorder, Illustrating How Constant-Draft Conditions Are Automatically Maintained by Hood-Draft Controller of Fig. 1

the kiln may be conducive to ring formation, and hence should be avoided. As a matter of fact, extreme variations in speed are not needed under ordinary circumstances if provision is made to control firing at the desired constant rate, and if adequate care is given to the preparation and delivery of material by the raw feeder. However, in cases where these requirements are not satisfied, especially when hood draft is not automatically regulated, attempts to operate in such a fashion, either by manual or automatic adjustment of the kiln speed controller, have resulted in speed fluctuations which could not be allowed.

Another development which provides for the same general operating philosophy of a constant combustion rate and variable kiln speed is illustrated in Fig. 3. One fundamental difference in the major plant equipment from that shown in Fig. 1 is in the method of cooling the clinker, that is, a so-called pressure cooler replaces the rotary type. In this case, one fan delivers air to the front section of the cooler grate and thence into the kiln hood

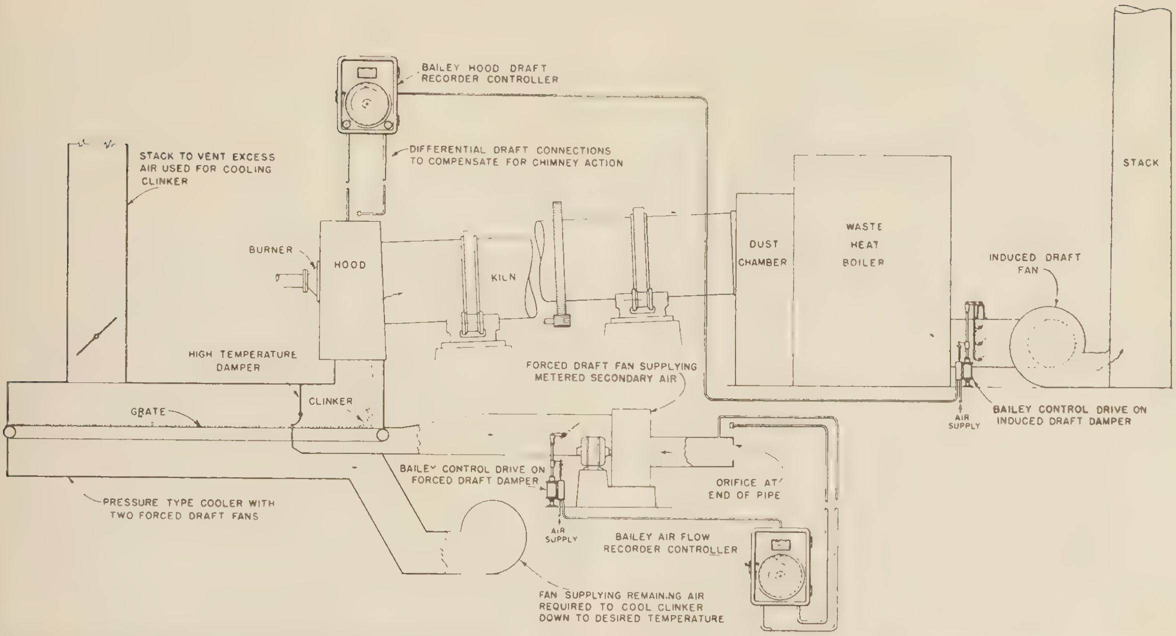

FIG. 3 SCHEMATIC DRAWING, DEMONSTRATING TYPE OF CONTROL REQUIRED FOR KILN WHEN SECONDARY AIR IS DELIVERED UNDER FORCED DRAFT

where it becomes secondary air for combustion, while another fan supplies additional cooling air to what may be termed the aftercooler. A primary-air fan draws hot air from the aftercooler and injects it into a blast pipe to act as the transporting medium for pulverized coal which is delivered by means of a helical screw.

It must be appreciated that the quantity of secondary air passing through the hot clinker to the hood will depend upon the thickness of bed and gradation of particles if the fan is operated at constant speed without compensating control. The variation in air flow would cause considerable difficulty in kiln burning. Consequently, a means is provided to establish the necessary air flow to meet combustion requirements and, thereafter, maintain the desired rate regardless of the variation in resistance to the passage of the air through the clinker to the hood. An orifice installed at the fan inlet produces a differential pressure which the instrument records in terms of air flow, after which the same mechanism functions as a controller by adjusting the damper in the duct leading to the cooler to hold the flow at the predetermined standard. Hood draft is also controlled by regulating the damper near the induced-draft fan for the purpose of maintaining a constant air leakage at the hood, to compensate for variation in resistance to gas flow through the kiln itself, and to aid in fixing the hot zone at the desired position in the kiln.

To complete the air-fuel setting, the speed of the coal feeder is adjusted to produce optimum combustion efficiency, an Orsat being used to analyze the gases. Again, it is found possible to operate in such a fashion long enough so that only periodic checks of the setting are required, say twice each day. The fuel-burning process is thus considerably simplified, and burners need only make occasional changes in kiln speed to obtain correct clinker temperature.

To demonstrate how satisfactorily the air-and-draft regulation is accomplished, Fig. 4 is presented. The upper two chart records indicate that secondary air and hood draft are maintained at practically constant standards even though the control is subjected to an unusually difficult task. It is to be observed that feed-end draft increases steadily from a value of about —0.15 to a magnitude of approximately —0.35 in. of water during the 24-hr period. The increased draft loss across the kiln is caused by the building up of rings. Hence, the draft controller must function in a manner to increase feed-end draft to overcome the additional resistance to gas flow. If this were not done, an increased pressure would develop at the hood which would change the air leakage through openings and cause the hot zone to move closer to the front of the kiln.

DRAFT CONTROL FOR ROTARY KILNS

At this point, it might be well to correct a common misconception concerning draft control as applied to rotary kilns. Prior to the two installations of equipment just described, cement-mill operators for many years talked about draft and its importance in maintaining satisfactory operating conditions, but they thought in terms of draft at the feed end of the kiln, not at the hood. Consequently, the very first attempt at draft control called for the draft connection to be made in the dust chamber at the raw-feed end, as shown in Fig. 5. This idea would be acceptable if the resistance across the kiln did not change, but the resistance is continually changing because of ring formations, both clinker and coal, and variations in level of material at various points throughout the kiln length. No one would consider a suggestion to control furnace draft in a steam generator by making the draft connection in the breeching leading to the stack, yet such an arrangement is analogous to the effort to regulate conditions in the front of the kiln by means of draft control at the feed end. The analysis, based on Table 1, should tend to clarify the situation by exposing the error in conception.

TABLE 1 HYPOTHETICAL CORRELATION BETWEEN GAS FLOW THROUGH KILN AND DRAFT IN DUST CHAMBER

Gas flow	Draft, inches of water
0	—0.5
2	—0.3
3	—0.2

Suppose the kiln is completely closed due to a solid ring; there

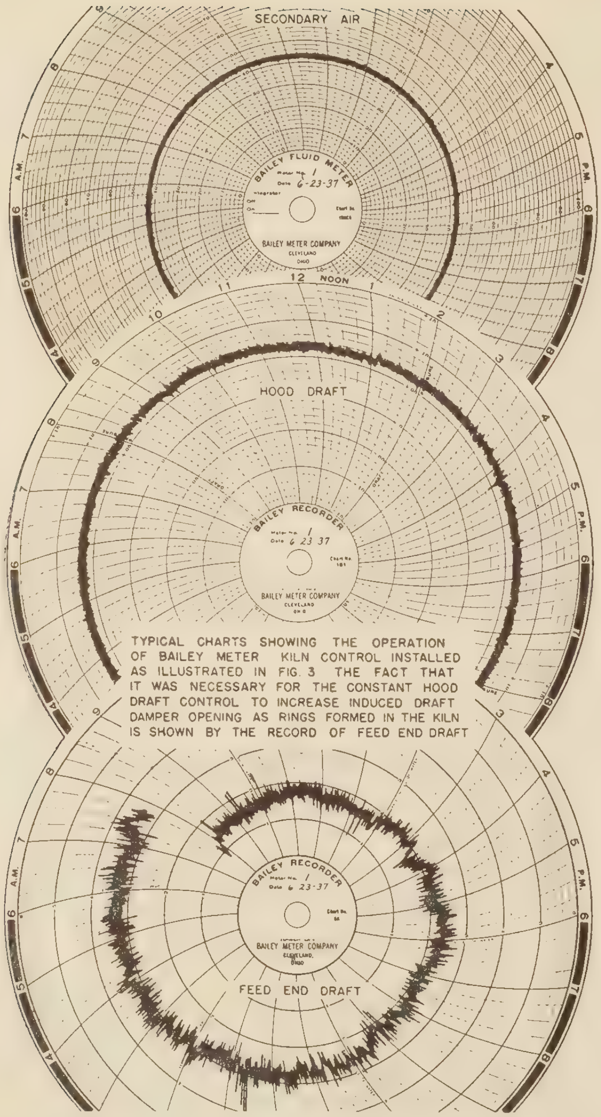

Fig. 4 Reproductions of Charts Showing Operation of Kiln-Control System, as Illustrated in Fig. 3

(The fact that it was necessary for the constant-hood-draft controller to increase induced-draft damper openings, as rings formed in the kiln, is shown by the record of raw-feed-end draft.)

is zero gas flow, and the draft in the dust chamber is a maximum, say —0.5 in. of water, as long as the gas in the stack remains at operating temperature. On the other hand, if the kiln is only partially obstructed, the flow of gas might be represented by a value of 2, while because of the gas flow the draft in the chamber will be somewhat lowered, say to —0.3. Under normal conditions with the kiln wide open, the flow may be represented by 3 and again the draft would be lower, say —0.2. Now, assume that a check on combustion conditions and the position of the burning zone is made when the situation within the kiln is normal, that is, gas flow equals 3 and draft is —0.2 and further, a draft controller is attached as illustrated in Fig. 5. Suppose a ring begins to build up in the kiln. Several undesirable results ensue. The first is a decreased gas flow because of the decreased opening. This causes increased feed-end draft. For example, if the flow is reduced to 2, the draft will increase to —0.3, as shown in Table 1. The second undesirable result now follows, for the control will function so as to restore the draft to the predetermined standard of —0.2, further reducing gas flow. This is not at all desirable, because raw feed and coal feed have remained unchanged. Obviously, feed-end draft control acts in a manner exactly contrary to that of a proper scheme, whereas control of hood draft maintains the correct conditions as long as there is sufficient draft created by the stack to overcome the additional draft losses caused by the restrictions.

The schematic layout of another type of control system is also shown in Fig. 5, in which an attempt is made to regulate the air-fuel ratio continuously even when the fuel rate is varied by the

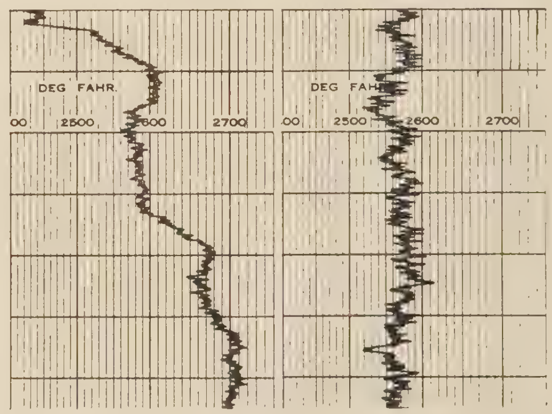

Fig. 6 Charts Taken From Recorder of Radiation Pyrometer Measuring Burning-Zone Temperatures

(The chart at the left indicates results when the burner gave no attention to the instrument, while the chart at the right shows the record when the instrument was used as a guide.)

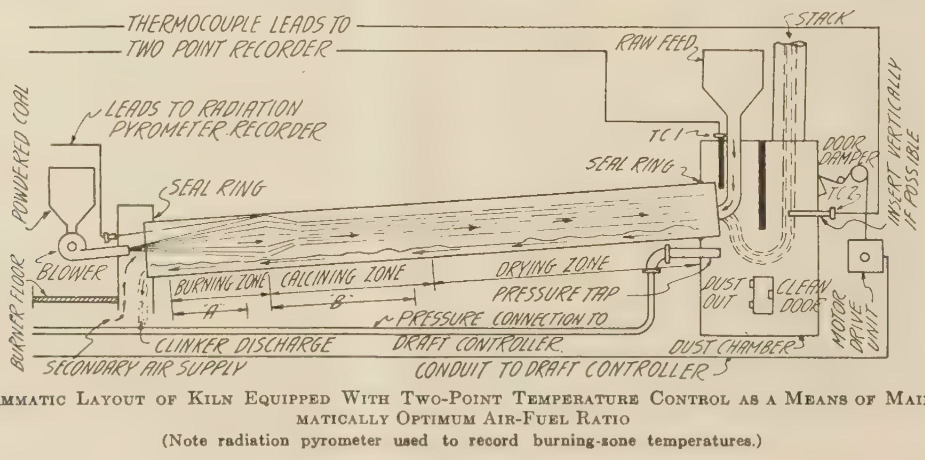

Fig. 5 Diagrammatic Layout of Kiln Equipped With Two-Point Temperature Control as a Means of Maintaining Automatically Optimum Air-Fuel Ratio

(Note radiation pyrometer used to record burning-zone temperatures.)

burner. The major equipment is similar to that shown in Fig. 1, except that a comparatively long dust chamber connects the kiln to the stack. A thermocouple is installed so that it projects into the kiln and another is located far enough away in the dust chamber in the path of the gases so that an appreciable temperature drop occurs, due to air leakage around the tail seal and loss of heat from radiation. A potentiometer style of instrument, utilized to act as a recorder-controller, is designed to register continuously the temperature differential between the two couples. From Orsat analyses, the normal temperature drop under actual operating conditions can be determined when there is no unburned gas in the stream at the feed end, and the controller can be adjusted to maintain this differential. For instance, if the burner notices that the clinker temperature is too low, he may increase the coal feed which, if sufficient to cause a deficiency of air, will introduce some unburned gas in the stream at the feed end of the kiln. Experience shows that combustion is at least partially completed by the air which leaks past the seal and, consequently, the heat thus developed raises the temperature of the second thermocouple. This action decreases the differential as registered by the instrument, which then operates to adjust a check damper to increase the air flow to the kiln hood. The control continues to increase air flow until the original value of temperature differential is restored. On the other hand, if fuel flow is decreased, it is found that the temperature differential increases, and the controller operates to decrease the air flow to maintain the desired conditions. In such a fashion, the correct air-fuel ratio is continuously maintained within certain limits. Actually, the range of control of fuel feed is comparatively narrow; yet it is extremely helpful to burners when they are asked to keep the clinker temperature within close bounds.

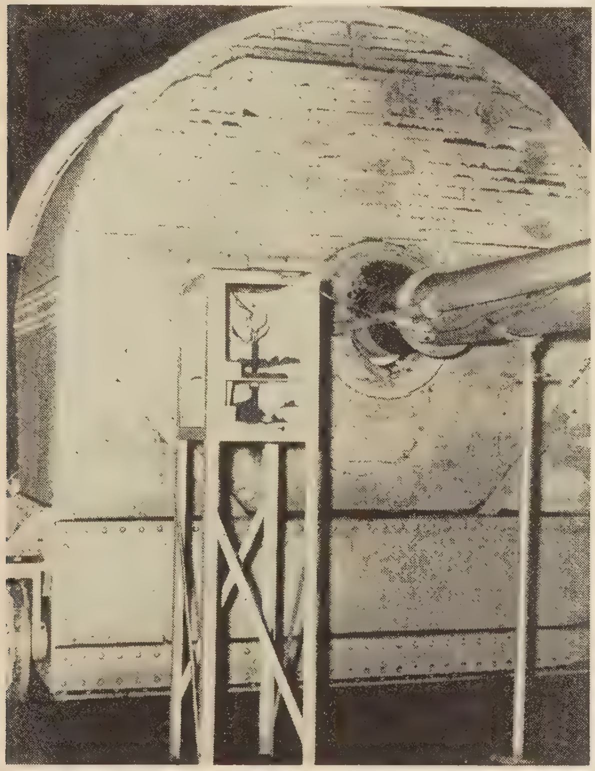

Fig. 7 Rayotube Mounted in Front of Kiln

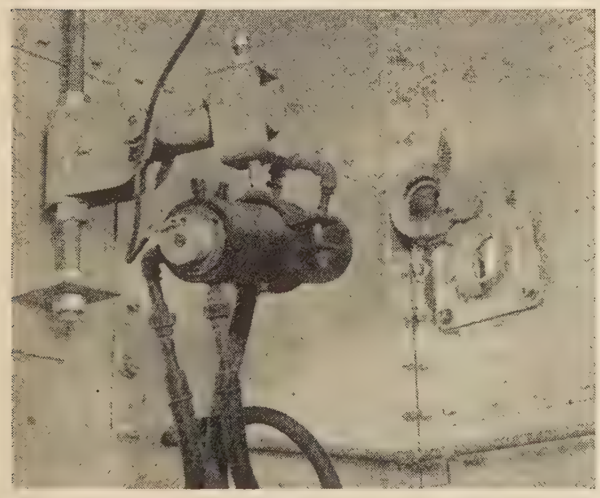

Fig. 8 Rayotube Sighting Through Hole in Kiln Hood
This instrument has a water jacket and is supplied with compressed air to prevent the entrance of dust, smoke, or flame.)

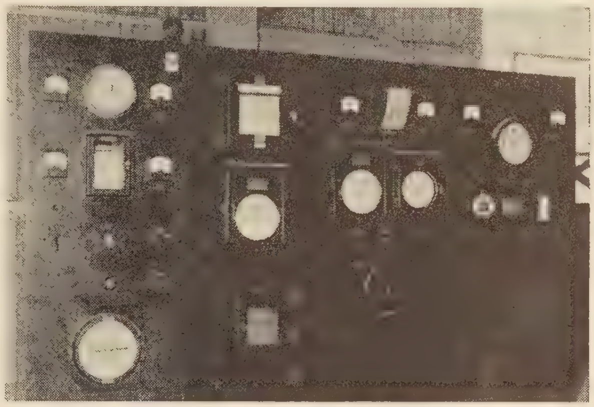

Fig. 9 Instruments and Control Equipment Mounted on Suitable Panel Board in Modern Kiln Department

In this type of installation, burning is controlled by varying both kiln speed and combustion rate, a radiation pyrometer being used for a temperature guide. As an example of the value of such an instrument to a burner, Fig. 6 is included. The chart at the left indicates the extreme variation in temperature in the burning zone when the burner gave no attention to the instrument, while the one at the right shows how closely the temperature was maintained when the burner used the instrument as a helpful guide.

Figs. 7 and 8 demonstrate two methods of positioning the rayotube element of such a temperature-recording instrument. It is to be noted in Fig. 8 that the device is equipped with a water-cooled jacket. Thus, provision is made for a stream of water to maintain the equipment within optimum operating temperatures, as well as for a jet of air to prevent the entrance of dust, smoke, or flame.

For the purpose of showing the close attention which is now given to obtain a satisfactory mounting of controls and instruments, a typical panel board is illustrated in Fig. 9. Included on the board are recorders and indicators used in conjunction with a radiation pyrometer, hood-draft controller, a fuel controller for a unit pulverizer, and various thermocouples for gas- and air-temperature measurement. This exhibit shows the extent to

which progressive mill operators are exerting their efforts to centralize control of the burning process and to eliminate the guesswork common in manual operation.

Co-ordinated Control System for Automatic Operation

Finally, the author wishes to propose a new scheme, one which provides a co-ordinated control system for the automatic operation of rotary kilns. Some may wonder why clinker burning is not controlled, like many other manufacturing processes, to maintain a predetermined production rate. The plan to be described aims to do just that, for the basic principle upon which the system functions is the second ideal of operation, namely, the preservation of a fixed speed of kiln and modification of the supply of air and fuel to secure the desired burning temperatures.

The major plant working equipment is illustrated schematically in Fig. 10. The raw mixture is supplied to the kiln by a suitable feeding device located at the high or raw-feed end. As the kiln rotates, the material passes down the kiln through the burning zone to be discharged as clinker to the perforated shaking grate of a pressure-type cooler. Air for cooling the hot particles is provided by a forced-draft fan. The air-quenched clinker passes from the cooler to the atmosphere through a swinging gate, or if further cooling is necessary, an aftercooler may be employed. In this event, an additional fan might be used to supply the air, or one fan of greater capacity could be arranged to discharge into a divided duct. Fuel is prepared in a unit air-swept pulverizer from which the coal is delivered to the kiln through the burner pipe. A portion of the air which cooled the clinker is drawn away from the cooler by the primary-air fan to dry the coal and transport it in suspension to the kiln. The remainder of the air passing through the clinker bed enters the hood to complete combustion of the fuel.

The procedure of operation, as previously stated, aims to establish a predetermined production rate. Thus, by trial, the optimum kiln speed is determined. Thereafter, it will remain constant, unless there is a pronounced change in the character of the raw mixture or in the type of product desired. At the same time, the optimum speed of the raw feeder is experimentally established and will remain fixed unless an emergency arises. Under these circumstances, what are the requirements of an ideal control scheme? Obviously, an adequate system should maintain the proper heat release to produce specified clinker temperatures. Further, it should maintain optimum combustion efficiency, that is, hold the air-fuel ratio continuously at the value which gives the best over-all economy.

In order to understand how the co-ordinated kiln-control system functions, it is important first to examine the method of regulating fuel flow to the kiln. As is well known by those familiar with the characteristics of an air-swept coal pulverizer, the quantity of fuel discharged is substantially proportional to the rate of flow of primary air through the unit, if a proportionate amount of coal is maintained therein. A controller is thus designed to vary the speed of the raw-coal-feeder motor to maintain a definite ratio of coal in the mill to the existing primary-air flow. The basis upon which this control operates is the relation between two differential pressures—one, the pressure drop across the mill proper; and the other, the pressure differential across the orifice in the air-supply line to the pulverizer. By such an arrangement it is possible to regulate the rate at which coal is delivered to the kiln by adjusting the damper which controls the flow of primary air. If an increased coal flow is demanded, the primary air is increased in proportion to the increase called for, and vice versa.

Now, consider that by trial the most desirable conditions of burning have been established. This means kiln and raw-feeder speeds are set. Heat release is sufficient to raise the temperature of the clinker to the desired standard. Combustion efficiency is at the optimum value, and the hood-draft controller has been adjusted to give the desired balance between forced and induced draft.

Then suppose a change occurs which decreases the temperature in the burning zone. The co-ordinated control apparatus, illustrated in Fig. 10, immediately functions. A photoelectric cell, sighted at the experimentally determined correct spot in the kiln, indicates that the temperature is too low, which means that the

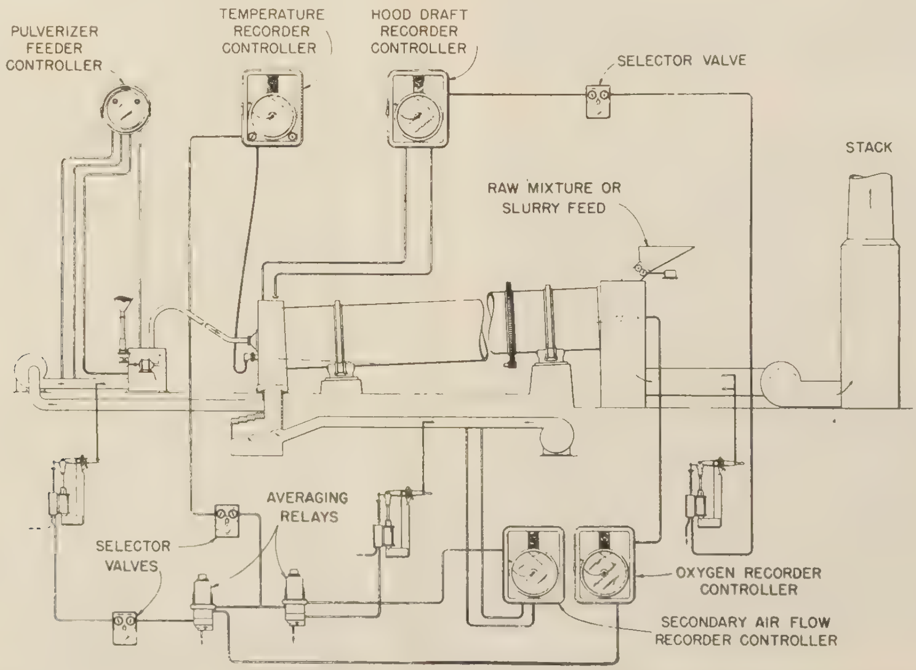

Fig. 10 Diagram Showing Co-ordinated Control System for Automatic Operation of Rotary Kiln

heat release is insufficient. The control operates to increase air and coal so that enough heat will be liberated to restore the temperature to the desired standard. A change in air flow is produced by a mechanism which positions the damper in the main air duct. This mechanism includes a metering device which operates through an averaging or two-element relay to establish a definite air flow rather than just a new damper position for each control impulse. Coincidental with the air increase, the same control impulse from the photoelectric cell increases fuel flow from the pulverizer. This latter action is effected by suitable means through a power drive which adjusts the damper controlling the flow of primary air to the unit mill.

Meanwhile, the exit gases are being continuously analyzed, preferably for oxygen content. A device capable of performing such a function acts as a recorder and as a controller to readjust the coal flow to maintain the optimum percentage of oxygen, since variation from such a value represents change in combustion efficiency. Impulses from this controller pass through the other averaging relay to readjust the primary-air damper. By this means, it is possible to compensate for the following:

1 Damper characteristics, that is, dampers of practical form do not necessarily work together to produce proportionate changes. For instance, to increase heat release, a new air flow is established in the main duct and, at the same time, the damper in the primary-air pipe is opened. It is not likely that both dampers have identical flow characteristics and hence the air-fuel ratio would vary.

2 Nonuniform performance of pulverizer, that is, relatively minor variations in the amount or character of coal within the pulverizer may cause momentary fluctuations in the Btu input of fuel to the kiln. In this connection, it might be pointed out that considerable progress has been made toward improving such characteristics of a unit pulverizer, yet further improvement is very much needed

3 Nonuniform coal, that is, the chemical analysis of the coal may vary to some degree.

The control makes one more significant adjustment when the increased heat release is demanded. Naturally, with a greater flow of air and fuel to the kiln, more combustion gases are generated and the damper at the induced-draft fan must be opened to exhaust the greater volume. Otherwise, the pressure in the hood would increase to cause greater air and gas leakage through openings and, in addition, the burning zone would move closer to the kiln front. Thus the purpose of the draft controller is to insure that combustion gases are carried away continuously from the burning zone through the kiln at the same rate at which they are generated.

In conclusion, a word is in order pertaining to the importance of continuous gas analysis as an essential guide in any fuel-burning process. Engineers have long realized the potential value of obtaining the oxygen content of combustion gases without the necessity of first analyzing for CO_2, for such a measurement is almost a direct determination of excess air. At the present time, there is at least one satisfactory device available to perform this function, and others are in the process of development. Consequently, there need be no delay in contemplating experimental work on the proposed system of control simply from the lack of such type of combustion-efficiency instrument. It is hoped that the suggestions which are outlined in this paper may create sufficient interest so that some effort in this direction will soon be forthcoming.

Acknowledgments

The author is grateful to the Leeds and Northrup Company and the Bailey Meter Company for the splendid co-operation extended by both organizations in the preparation of illustrative material for this paper.

Discussion

C. S. Burnett.[3] The author of this paper is to be congratulated on the presentation of a method of automatic kiln control which is apparently completely new as to ideas and completely automatic in its arrangement.

Control of burning-zone temperature automatically by regulation of the kiln fuel is not new, several installations now being at least partially automatic. However, as far as is known, none is capable of maintaining automatic operation a major portion of the time.

Kiln temperatures are relatively slow in responding to changes in fuel. If the temperature-controlling device is not properly compensated and adjusted to be in step with the speed of response of the temperature changes, a hunting cycle will result in which the fuel will chase the temperature up and down through a continuous cycle.

If some attempt is not made to change the air with and in approximately the proper ratio to the coal, smothering of the flame on increasing fuel, or excessive air and changed burning-zone position on decreasing fuel may result. Such instabilities limit the practical use of automatic temperature control.

It is, however, conceivable that, with air controlled in the proper proportion to the fuel, a greater stability of automatic operation would result.

The control arrangement proposed by the author is notable in that the air is the limiting factor. Coal cannot be fed by the control if there is insufficient air available to burn it. This feature is very desirable and has long been used in large steam-generating units, particularly where air, gas, or pulverized coal is used.

In considering the proposed arrangement, the plant operator will be concerned primarily with the sources of potential trouble. In studying the arrangement, it appears that there are several points to which particular attention should be paid.

The statement is made: "Meanwhile, the exit gases are being continuously analyzed, preferably for oxygen content." Since CO_2 is not a true indication of fuel-air ratio in a cement kiln, the analysis would necessarily have to be made by an oxygen-measuring instrument; and, since this instrument would be the heart of the system, we would all be interested in hearing more about it. Such a device should respond quickly to changes in fuel or air and, above all, should be able to operate for long periods without excessive maintenance being required.

The major sources of trouble in such an instrument would, no doubt, be in the sampling tube. This would, necessarily, be water-cooled and should be designed to prevent frequent stoppage by the kiln dust. Such a sampling tube is provided by at least one oxygen-measuring-instrument manufacturer.

Oxygen recorders have been used in power-generating stations for at least 2 years; hence, apparently, they have reached at least a semipractical stage of development. The usage they would receive around a cement kiln, however, would be much more severe than in power stations, particularly because of increased dust.

The present design of pressure cooler is not ideally arranged to permit fine control of secondary air. Designers have always considered the primary purpose of clinker coolers to be to cool clinker in order that it may grind more easily, or to quench the magnesia crystals in their amorphous state, in order to meet autoclave-expansion specifications. Now, we have a further use for these coolers.

[3] Alpha Portland Cement Co., Easton, Pa.

The arrangement, shown in Fig. 3 of the paper, is only partially satisfactory, as it is not possible to make the high-temperature-dividing damper very tight, and a considerable flow of air either away from or to the kiln would complicate matters.

Some thought in the design of clinker coolers to allow for better secondary-air control would be an effective step in advancing the cause of automatic kiln operation.

The system proposed by the author would, undoubtedly, be very desirable and, no doubt, practical in a kiln setup where there is an effective means of secondary-air control, furnace draft, and an accurate means of coal control.

There are, however, a great many kilns in service which, no doubt, will continue to be used, that are not arranged with the necessary equipment. It would be unfortunate if the developed instrument could not be applied to some of these existing kilns.

Considering a mill where there are several kilns discharging their gases into a common dust chamber and where kiln air is introduced only from the waste-heat fans, it is highly improbable that each of the kilns would get the same amount of air through it, as variations in coatings and other variables would affect its resistance to gas flow. With a draft controller maintaining the hood draft constant and approximately equal on all of the kilns, these variables would be efficiently removed.

The oxygen-measuring instrument could then be installed on each kiln, and from it the coal could be controlled to maintain the proper fuel-air ratio. Burning-zone temperature would be controlled by the kiln speed, and variations in the production of individual kilns could be regulated by varying slightly the value of the hot draft. Such a system does not have the flexibility of the author's scheme, but does allow the benefits of proper fuel-air ratio to be applied to this great number of existing kilns.

The discussion of the merits of controlled draft at the hood end of the kiln is well taken, and there is not much reason for discussion on this point.

The average modern steam-generating station is years ahead of the average cement plant in so far as utilizing combustion instruments to the fullest extent is concerned. It is true that central stations have their CO_2 recorders, steam and air flowmeters, and other fuel-air-ratio-efficiency instruments, which could not be adapted directly to our purpose.

The advent of the oxygen recorder, however, should fill a long-felt need in the cement industry, and it is hoped that this instrument can be developed to a point where it will be practical for use in the average plant.

It is suggested that the best way for the instrument manufacturer and the cement plant to get together for a mutually beneficial development would be to make a demonstration installation.

In the writer's district, there are numerous plants with equipment which would be adaptable to the proposed arrangement. Since this district produces much of the cement made in this country, it should be an ideal location for such an installation.

A. G. Christie.[4] Engineers who have studied cement production have marveled at the fact that so little has been done to apply control to the several steps of the process and particularly to rotary-kiln operation. Too often one is told that reliance can only be placed on the burner for proper operation. One who has watched burners handle a kiln must be impressed with the fact that much manipulation is unnecessary, because of the guesses made by the burner as to the cause of the trouble and the best method of correcting it. His decisions are based solely upon visual observation of the kiln interior without the aid of an accurate meter or device to inform him of the exact conditions. Some excellent indicating devices not widely used are available, such as the Smidth instruments, which assist the burner in diagnosing troubles and thus improve the efficiency of operation.

It is unfortunate that the author describes only briefly two of the systems now in use. By making operation fully automatic, less reliance is placed upon the skill of the burner and better average results are obtained. Before such systems are applied, many rotary-kiln installations should be largely rebuilt and modernized. For instance, relatively few kilns have proper preheating equipment for drying and preheating the contents of the slurry. Also, many old-fashioned clinker coolers could be profitably replaced by modern clinker air-quenching equipment which would lead to fuel savings, as well as to reduced power requirements for clinker grinding. Few kilns have fans for forced- and induced-draft control. When such kilns are modernized, automatic control can be considered.

While the control systems described in this paper have operated satisfactorily, much yet remains to be done to perfect kiln operation. In fact, further experience with such control systems must lead to improvements in the equipment itself and possibly to modifications of the kiln and its auxiliaries.

The author refers in a closing paragraph to the value of an oxygen analyzer for gases. The CO_2 content of the cement-kiln gases may come from the combustion of the fuel or from the calcining of the limestone, either of which may vary. Hence, this CO_2 as a measure of the efficiency of the combustion process is uncertain. On the other hand, the oxygen present must all come from the entering air, and its amount will serve as a measure of the excess air present. While this measurement is of value on cement kilns, an oxygen recorder on rotary kilns, burning lime or dolomite, would have equal value. A wide field for the application of a low-priced oxygen recorder would be its use on vertical lime kilns, of which there are hundreds in this country. In general, these vertical kilns have no instruments at present to indicate kiln conditions or to aid in control. However, many of them should be rebuilt or modernized before funds are expended on instruments or controls.

J. C. Witt.[5] The writer considers fuel control preferable to kiln-feed control, as outlined by the author. The industry is not yet ready for the completely automatic control of kilns (because of a number of factors), but this may come someday.

W. H. Sayler.[6] The writer's interest in the subject of this paper arises from the fact that his early professional life was spent in the cement industry, while the last several years have been devoted to the design, sale, and installation of automatic process-control systems.

In reviewing the paper, it will be helpful to consider the problem from a broader viewpoint than the author has been able to use, as his paper is confined basically to an excellent report of specific installations.

In a cement kiln we have the following variables:

1 The rate of feed of raw material.
2 Speed of kiln (in many cases fixed).
3 Rate of fuel feed.
4 Rate of air feed.
5 Air pressure in kiln.
6 Temperature in kiln.
7 Fuel-air ratio.
8 Heat input to raw-material input ratio.

[5] Technical Service, Manager, Marquette Cement Manufacturing Company, Chicago, Ill. Mem. A.S.M.E.

[6] Registered Professional Engineer, Specialty Sales Company, Salt Lake City, Utah.

Of these eight variables, 2 is the only one which can be maintained constant without automatic control. Variables 7 and 8 are really functions of 3 and 4 and 1, 3, and 4.

In the wet-process plant, control must start in the raw-grinding room. Unless the slurry is automatically controlled at constant density, a volumetric-type slurry feeder will introduce errors to begin with. Therefore, the slurry should be controlled to a constant density to obtain a uniform feed rate. In the dry plant, a constant-weight feeder should be used to insure the feed rate being the same as the management hopes it is. This eliminates variable 1 from the control problem. For this discussion we will assume variable 2 to be fixed.

The next important variable to be made constant is the air feed. When we remember that approximately 14 lb of air per lb of coal are required, or for a 1000-bbl-per-day kiln, 1,400,000 lb per day, it is seen that air is important in its effect on kiln economy. In the West, in many places, air temperature may vary tremendously over an 8-hr period. An examination of Weather Bureau reports shows that, at Salt Lake City, the density of air may vary, both because of temperature and barometric variation, as much as 13 per cent between 8 a.m. and 3 p.m. in clear summer weather. In case of sudden showers, the variation is more abrupt. During a 24-hr period, the variation is much greater.

Therefore, the writer proposes the following control scheme:

1 Meter raw material into the kiln at a truly constant weight rate (as described).

2 Meter air into the kiln, a constant weight ratio to raw-material feed.

3 Meter in the proper amount of fuel to react with the air at whatever ratio is decided upon as optimum.

4 Control draft at the firing hood.

5 Record kiln-firing-end temperature, if desired.

6 Record kiln-exit temperature.

7 Record, or occasionally check, oxygen content of flue gas.

Point 1: May be achieved by constant volume rate of slurry, if constant slurry density is maintained.

Point 2: May be maintained by a constant air-weight controller, such as has been applied to blast furnaces in the steel industry.

Point 3: May be handled by a standard air-to-fuel-ratio regulator.

Point 4: Adequately covered by the author.

Point 5: A record is sufficient in this case, since the precision of temperature measurement in the firing end of a cement kiln is not high enough to permit control by temperature.

Point 6: The record only is necessary, since this temperature is a measure of results.

Point 7: Most gas-percentage recorders are not precise enough to make reliable control mechanisms. This statement is open to dispute, but on a total oxygen percentage of, say, 1 per cent, in the flue gas, it is easy to compute the error in proportioning, caused by the oxygen-recorder reading 1.1 per cent when it should read 1 per cent.

Except for the oxygen recorder, with which the writer does not claim too great a familiarity, all of the devices described are more or less standard products with at least two nationally known manufacturers.

In conclusion, the writer wishes to express the hope that this paper will provoke a lively interest in the problem of applying automatic control to the cement industry.

Author's Closure

The author is grateful to those who have contributed discussions of this paper. Several thoughts expressed by the writers warrant further comment.

Mr. Burnett calls attention to the problem of applying control apparatus in a plant where a number of kilns discharge gases into a common flue. Obviously, satisfactory regulation of combustion requires hood-draft control on each kiln. The author has had considerable experience with just such a problem. A water-cooled sliding-gate damper was installed in the gas duct between the tail end of the kiln and the main dust chamber, while the draft measuring and controlling device was attached to the kiln hood. No difficulty in damper operation was encountered; only a small quantity of water was required to keep the damper reasonably cool; and hood draft was maintained continuously within limits of ± 0.005 in. of water. Such an arrangement can be thus utilized as part of a control layout in the type of plant to which Mr. Burnett refers. When clinker is discharged to rotary coolers or open pits, constant hood draft establishes the secondary-air supply; the O_2 controller maintains the desired fuel-air ratio; and burning-zone temperatures can be kept within required limits by changes in kiln speed, either by automatic adjustment from a sight temperature instrument or by manual control.

Professor Christie calls attention to the need for control development in the cement industry, especially as it concerns the rotary-kiln process. He points out that in many cases kiln installations need to be rebuilt and modernized before regulating apparatus can be applied with benefit. The great difficulty in the past has been to convince the many mill operators of the economic advantages of such rehabilitation. It should be of interest to know there are numerous instances where installation of controls, regulating just one element of the burning process, has directed attention to distinct shortcomings in major equipment. Modification of kiln and auxiliary design has brought about subsequent marked improvement, and further use of automatic control devices has been thus encouraged.

In general, the discussions emphasize the need for continued effort and experimentation, in order that rotary-kiln operation may approach the high degree of excellence already existent in many other manufacturing processes involving the combustion of fuels. It was not many years ago that complete automatic control of steam boilers was considered an ideal to be realized only in the distant future; today, this goal has been reached and a complete set of control appurtenances is an integral element of all modern steam-generator installations. Energetic research, sponsored by those responsible for the most efficient operation of rotary kilns, will accomplish a similar much-needed result.

A Method of Estimating the Circulation in Steam-Boiler-Furnace Circuits

By A. A. MARKSON,[1] T. RAVESE,[2] and C. G. R. HUMPHREYS[2]

The estimation of the quantity of circulation in modern high-pressure boiler-furnace circuits is not essentially new, especially to the literature abroad. Methods popularized by Münzinger and others are based on an air-lift analogy and, while straightforward, are tedious of application. The method developed by the authors is essentially an inversion of the problem as previously conceived. It consists of solving a simple equation by the use of parametric circulation curves for the heat absorption corresponding to the leaving quality of the mixture. These are given for two assumed conditions of heat transfer, that of principal heat absorption at the bottom of the tube, and that of uniform heat absorption at the length of the tube up to the critical pressure. Most commercial applications are intermediate between these two assumptions. Examples are worked out in detail to show the application. Some effects of changing circuit design are illustrated. A method of obtaining the point of maximum circulation with respect to heat absorption directly is outlined.

The following nomenclature is used in the paper:

A = internal circuit area
D = tube diameter
d = density, lb per cu ft
d_1 = density of solid water, lb per cu ft
d_2 = density of mixture leaving circuit, lb per cu ft
d_{22} = logarithmic-mean density in heated circuit
F = frictional losses
f = friction coefficient
G = mass flow, lb per sq ft per sec
g = 32.2
H = total heat absorption of circuit, Btu per hr
h_{fg} = enthalpy of vaporization, Btu per lb
l = vertically projected length of circuit, ft
l_1, l_2 = developed length of circuit, ft
N = number of risers or downcomers
Q = heat absorption, Btu per sq ft per hr
P = pressure
p = pressure drop in tube, as defined
V = velocity
v = specific volume, cu ft per lb
v_f = specific volume saturated liquid, cu ft per lb
v_{fg} = volume of vaporization, cu ft per lb
W = rate of flow, lb per hr
w = rate of flow, lb per sec
X = steam quality of mixture

The exact formulation of the quantity of circulation produced in the furnace circuits of an operating steam boiler is obviously of extraordinary complexity. The major evaporative zone of a modern high-pressure-boiler unit is the water-cooled furnace and first row of boiler tubes. From a hydraulic standpoint, these circuits lend themselves more to analysis than do those of the older units where the sectional boiler with its baffling constitutes the principal evaporative section.

Münzinger (1)[3] published a method of calculating boiler circulation which has since been used by many writers. Two recent papers in English by Van Brunt (2), and by Lewis and Robertson (3), illustrate the use of Münzinger's method. Briefly, it consists of analyzing the boiler circuit as though it were an air-lift pump.

Curves of hydraulic loss are plotted against velocity, usually for constant heat-absorption rate along the tube. The curves of available head, due to the density differences, are also plotted against velocity at constant heat absorption. The intersection of the loss and head curves marks the theoretical operating point of the unit for the assumed conditions.

The principal assumptions usually made in connection with these analyses are:

1 The rate of heat absorption is uniform along the heated tubes, and the heat absorbed per tube is the same.

2 The mixture of steam and water is essentially homogeneous. Bubble slip is neglected.

3 The coefficient of friction is usually taken as a constant throughout.

4 Individual hydraulic resistances are handled by some conventional method.

5 Evaporation starts immediately and there is no steam in the downcomers.

6 Drum velocities are negligible.

Each of these assumptions is open to criticism having varying degrees of validity. Nevertheless, the conclusion that approximations of value can be derived from them is not open to very serious objection (3), especially for the higher operating pressures where the steam and water phase differences become less marked.

While the artifices to be discussed constitute an important phase of the theory of boiler circulation, it is well to emphasize the fact that a complete picture of circuit design is not to be gained from a steady-state mechanism. It suffices to state as an example that a circuit having a low resistance also has a low damping characteristic. Tubes may never burn out in such a circuit but slight disturbances in operation conditions may produce annoying oscillations in water level.

The authors' method differs from Münzinger's. In the Münzinger method, simultaneous curves of available head and of losses against velocity must be drawn for each assumed condition, giving one set of curves to be constructed for each point. The construction of a complete circulation-heat absorption characteristic curve is therefore a drawn-out affair. The present

Contributed by the Fuels Division and presented at the Fall Meeting, Louisville, Ky., October 12–15, 1941, of The American Society of Mechanical Engineers. This paper was also presented under the auspices of the Applied Mechanics and Power Divisions at a meeting of the A.S.M.E. Metropolitan Section held at Columbia University, New York, N. Y., November 18, 1941.

[3] Numbers in parentheses refer to the References at the end of the paper.

method inverts the problem. The resistance of the circuits having been formulated, an assumption is made as to the quality of the mixture coming from the circuit. A set of parametric curves is presented by which a basic equation is solved for the rate of heat transfer which must correspond to this quality. Having these, the velocity, mass flows, and other derived quantities are readily calculated.

The parametric curves of the circulation or Z function possess considerable interest by themselves. Constant heat absorption is represented by a horizontal line on the curves, so that, having located an operating point for an actual boiler on the diagram, the rough operating characteristic for this or an identical boiler at different pressures and heat absorptions may be quickly predicted. Such comparisons are less accurate if carried over too wide a range, because this procedure neglects secondary density effects.

Development

Throughout, all losses and heads will be expressed as head in feet of a column whose density is that of the mixture leaving the circuit. All velocities will be expressed in terms of the velocity leaving the circuit. This is convenient because there are usually but three densities involved, i.e., the density of solid water, the mean density of the heated column, and the actual density of the mixture leaving the circuit.

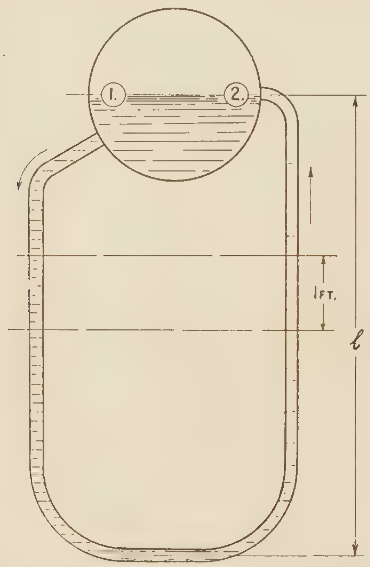

Fig. 1 U-Tube Circuit Connected to Drum

A comparison of the method with others indicates that the basic assumptions and the evaluation of the resistance coefficients are the same. The results obtained should be identical. The introduction, however, of the graphical parameters saves considerable purely mechanical labor and gives a better over-all picture of circulation, considered as a hydraulic process.

A considerable simplification can be achieved for some purposes in setting up the resistance coefficients by the device of adding so many pipe diameters to the friction length. Where this can be done discriminately the results should be good.

Fig. 1 is a U-tube circuit connected to a drum. The assumptions will be made that the tubes are heated on one leg, and that the feed, entering the heated section, is at the steaming point. It will also be assumed in a purely introductory way that (as in many modern boiler furnaces) the principal heat absorption is at the bottom so that, neglecting gravity head, the tube acts as though the mean density were roughly constant throughout the length. Thus, the mean density in the heated leg may be taken as approximately equal to the density leaving the tube. It will be shown that this assumption does not lead to radically different results than the assumption of uniform steam generation throughout the tube, which represents another extreme of practical operation.

By taking a 1-ft section across the tube, the gravitational head per foot of vertical length in terms of a column having a density d_2 is

$$\frac{d_1 - d_2}{d_2} \qquad [1]$$

and for the total length, l is

$$l\left(\frac{d_1 - d_2}{d_2}\right) \qquad [2]$$

where d_1 is the density in the downcomer and d_2 the average density in the riser. This head is the driving force of natural circulation. Balancing the available head are the appropriate circuit losses.

The section, under consideration in Fig. 1, is from point 1 in the drum to point 2 in the drum at the same elevation as point 1. The energy of circulation is wholly derived from the isothermal changes of state in evaporation. The circuit may be analyzed hydraulically by considering the forces which balance the head of circulation. The available head is considered as established by the density differences in the heated and unheated parts. This head is consumed or balanced by various losses occurring in the circuit. The losses, expressed in velocity heads, are equated to the head of circulation in a manner analogous to the application of the Bernoulli theorem. It may be easily shown that this procedure in its details lacks thermodynamic and even hydraulic rigor, but this lack is unimportant. It is equivalent to stating as a theorem that the net gravitational work done between points 1 and 2 is zero.

Consider 1 lb of water at saturation temperature at point 1. It enters the tubes with an entrance loss. There are further losses accountable as friction and change of section up to the evaporating tubes. There, the state commences to change and the similar losses from this point on must take this into account. At the discharge point 2, which is assumed to be at the same level as point 1, the mixture is delivered at some velocity into the drum. The drum velocity is assumed as zero. The use of the term "acceleration loss" has been introduced by practically every writer on the subject of boiler circulation to account for the reactive head which is developed when the particles, initially traveling with the velocity of solid water, are accelerated by the evaporative process in a section of constant cross section. Lewis and Robertson (3) go into considerable detail on this matter to explain that the reactive force rather than the whole exit kinetic energy should be balanced against the available head, because the excess energy has been generated directly by the fire as part of the latent-heat change. But the authors feel that it might be better, since the entire process of circulation stems from the change of state, to regard acceleration loss as an engineering coinage in accounting for part of the head. However, there is no doubt of its physical meaning. It is one of the principal forces involved in "pop-bottle" action in boilers. The foregoing is not meant to imply novelty other than of name for this, as every work on theoretical hydraulics and thermodynamics considers this force in the pipe-line flow of compressible fluids (4).[4]

[4] The concept of acceleration head stems directly from the general equation

$$-vdp = \frac{VdV}{g} + dF + dl$$

which is in effect integrated by the methods of the text.

Frictional losses will be defined quite conventionally as consisting principally of downcomer and riser friction amenable to treatment by the friction formula of the form

$$\frac{p}{d} = \frac{4flV^2}{2gD}$$

where

p = pressure drop, lb per sq ft
d = density of fluid, lb per cu ft
f = friction coefficient
V = velocity, fps
D = internal tube diameter, ft

These losses are reducible to a standard form in terms of d_2 and V_2.

Let A_1 be the combined area of all the downcomers and A_2 be the area of the risers. The riser friction in feet of d_2 is written as

$$\frac{4fl_2V_2^2}{2gD_2}$$

The downcomer friction likewise is

$$\frac{4fl_1V_1^2}{2gD_1} \text{ in feet of } d_1$$

To transform the downcomer friction into terms of V_2 and d_2 use the continuity expression

$$A_1V_1d_1 = A_2V_2d_2$$

giving for the downcomer friction in feet of d_1

$$\frac{4fl_1}{2gD_1}\left(V_2\frac{A_2d_2}{A_1d_1}\right)^2$$

Multiplying by $\frac{d_1}{d_2}$ transforms this into feet of d_2 reducing to

$$\frac{4fl_1}{2gD_1}\left(V_2^2C^2\right)\frac{d_2}{d_1}$$

where

$$C^2 = \left(\frac{A_2}{A_1}\right)^2$$

Kinetic Losses. This term will be taken to include all losses due to entrance, changes of section, and dissipated velocity up to the evaporating section.

These losses may be approximated as a function of V_2^2 and become on transformation similar to the foregoing

$$\frac{k_1V_2^2C^2}{2g}\cdot\frac{d_2}{d_1} \text{ in ft of } d_2$$

where k_1 is the summation of the usual loss coefficients. To these may be added similar evaporating-circuit losses, including moisture baffling, and drum losses as

$$k_2\frac{V_2^2}{2g} \text{ in ft of } d_2$$

k_1 and k_2 are evaluated as in ordinary hydraulic work.

Acceleration Loss. If w is the weight of fluid per second, its change of momentum due to evaporation is

$$\frac{w}{g}\left(V_2 - V_i\right)$$

where V_i is the inlet velocity to the heated section. The change of momentum per second is also numerically the reactive force. This, divided by area, gives pressure, and again by d_2 gives loss in feet of d_2, becoming

$$\frac{w}{d_2A_2g}\left(V_2 - V_i\right)$$

For V_i write $V_id_1 = V_2d_2$

$$V_i = V_2\frac{d_2}{d_1}$$

and finally after transformation the acceleration loss becomes in feet of d_2

$$\frac{V_2^2}{2g}\left(2 - 2\frac{d_2}{d_1}\right)$$

Collecting all the losses as a coefficient of $\frac{V_2^2}{2g}$ gives

$$\begin{aligned}\Sigma \text{ losses, ft } d_2 = \frac{V_2^2}{2g}\Bigg[&\frac{4fl_2}{D_2} \text{ risers}\\
&+\frac{4fl_1}{D_1}C^2\frac{d_2}{d_1} \text{ downcomers}\\
&+k_1C^2\frac{d_2}{d_1} \text{ kinetic on water circuit}\\
&+k_2 \text{ kinetic on steam circuit}\\
&+2-2\frac{d_2}{d_1}\Bigg] \text{ acceleration}\end{aligned}$$

$$= \frac{V_2^2}{2g}\left(\frac{4fl_2}{D_2} + \frac{d_2}{d_1}\left[\frac{4fl_1}{D_1}C^2 + k_1C^2 - 2\right] + k_2 + 2\right)\ldots[3]$$

This expression is equal to the available head which is $l\left(\frac{d_1 - d_2}{d_2}\right)$ giving

$$V_2 = \frac{(2g)^{1/2}\,l^{1/2}}{K^{1/2}}\left(\frac{d_1 - d_2}{d_2}\right)^{1/2}$$

where K is the coefficient of $\frac{V_2^2}{2g}$ in Equation [3]. For weight, we multiply by A_2d_2. Collecting constants

$$W = \frac{28{,}900\, A_2l^{1/2}\,d_2^{1/2}\,(d_1 - d_2)^{1/2}}{K^{1/2}}$$

where W is the rate of circulation in pounds per hour.

Multiplying by the quality and hfg, the heat absorption in Btu per hr

$$H = 28{,}900\cdot\frac{A_2l^{1/2}}{K^{1/2}}\,d_2^{1/2}\,(d_1 - d_2)^{1/2}\cdot X\cdot h_{fg}$$

$d_2^{1/2}\,(d_1 - d_2)^{1/2}\cdot X\cdot h_{fg}$ can be represented graphically by Fig. 2 as Z, so that the circulation equation reduces to the form

$$H = 28{,}900\cdot\frac{A_2l^{1/2}}{K^{1/2}}\cdot Z\ldots\ldots\ldots\ldots\ldots[4]$$

This result was based upon the hypothesis of principal heat absorption at the bottom of the circuit. It is pertinent to inquire how this compares with the assumption of uniform heat absorption along the tube, for between these two assumptions lies most of the cases encountered in practice.

We start with the unbalanced driving force due to uniform generation of steam, assuming no bubble slip.

The mean density of such a column in terms of d_1 and d_2 is

$$d_{22} = \frac{2.3}{Xv_{fg}}\log_{10}\left(\frac{d_1}{d_2}\right)$$

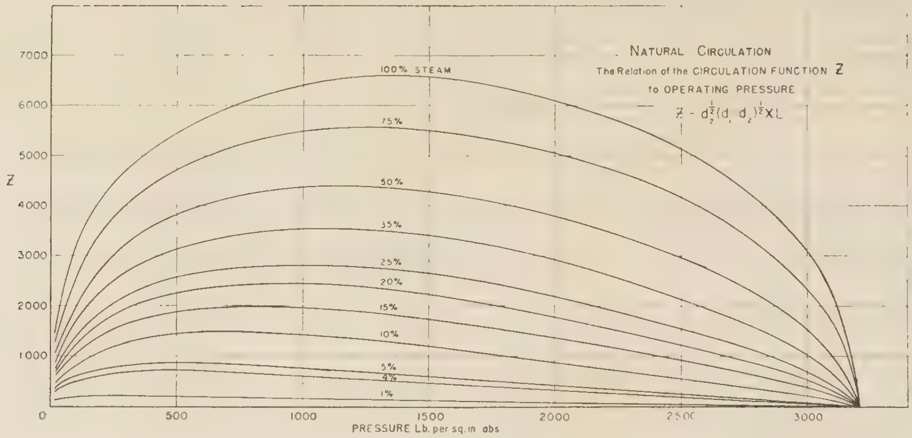

Fig. 2 Natural Circulation: Relation of Circulation Function Z to Operating Pressure

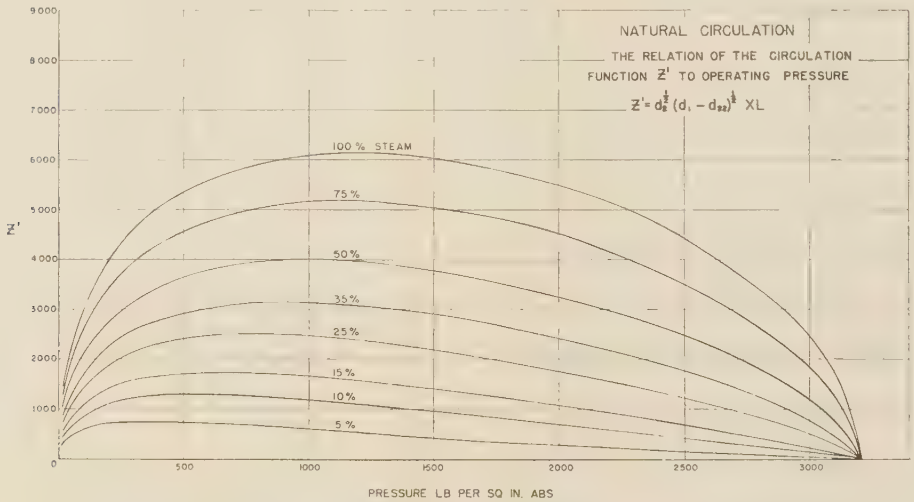

Fig. 3 Natural Circulation: Relation of Circulation Function Z' to Operating Pressure

as derived in Appendix 1, where d_2 as usual is the density leaving the tube. In terms of d_2 the unbalanced head is $\frac{d_1 - d_{22}}{d_2}$, per foot.

We may write

$$l\left(\frac{d_1 - d_{22}}{d_2}\right) = K'\frac{V_2^2}{2g}$$

where K' is a loss coefficient.

In this loss coefficient, all the losses but the riser friction are defined much the same as by Equation [3]. The riser friction, however, does not depend upon V_2 but must follow the changing velocity and density along the tube. Term K' must correctly estimate the riser friction.

A better friction term for use in K' is

$$\frac{4fl_2}{D}\left(\frac{d_2 + d_1}{2d_1}\right)$$

as derived in Appendix 2. Thus, the riser friction term in K' for uniform heat absorption becomes

$$\frac{4fl_2}{D_2}\left(\frac{d_2 + d_1}{2d_1}\right) = \frac{4fl_2}{D_2}\left(\frac{1}{2}\cdot\frac{d_2}{d_1} + \frac{1}{2}\right)$$

By a process similar to that followed in deriving Equation [4], an expression relating the circulation to the heat absorption when the heat is uniformly absorbed is readily obtained as

$$H = \frac{28{,}900\ A_2 l^{1/2}}{(K')^{1/2}} Z' \qquad [5]$$

where $Z' = d_2^{1/2}(d_1 - d_{22})^{1/2} \cdot X \cdot h_{fg}$. Term Z' is represented graphically in Fig. 3. It is the authors' conclusion that all practical cases to which these methods may be applied will lie between the principal assumptions of heat absorption as given.

Application

The application of the method to a furnace circuit of assumed characteristics will be shown. The circuit consists of 161 riser tubes of 3 in. OD, shown at top of work sheets, Figs. 4*a* and 4*b*. It is supplied by two 12-in-ID downcomers. The projected heating surface is 2700 sq ft. The vertical height is 50 ft. The developed length of the risers is taken as 90 ft and the downcomers as 60 ft. The assumed nominal rate of heat absorption is 49,000 Btu per sq ft of projected area per hr. Each tube absorbs the same quantity of heat. Densities of mixtures may be obtained from Fig. 5.

Example 1. The first problem will be to establish the circulation characteristics at 2200 lb abs as a function of heat ab-

FIG. 4*b* STEAM-AND-WATER CIRCUIT AND WORK SHEET FOR 2200-PSI BOILER PROBLEM, EXAMPLE 2

sorption for both the cases of bottom and uniform heat absorption. Fig. 4*a* shows the computations made on the work sheet which was used and found to be convenient. Values of X are assumed; K is calculated for each value of X. The value of Z is obtained for 2200 lb from the Z curve for each value of X. The basic equation is then solved for H, the total heat absorption. Given X and H, the total weight per hour circulated is obtained. This divided by the appropriate area and time unit gives the mass flow G in pounds per second. Term G multiplied by the specific volume gives the velocity. The process is also undergone for the case of uniform heat absorption. The results are given in Table 1 and Fig. 6. Term f is taken as 0.005 throughout.

Example 2. The next application is the problem of defining the circulation characteristic of this circuit as pressure varies with constant heat absorption for both the case of uniform and bottom heat absorption. (See Fig. 4*b* for work sheet.) The riser-tube diameters have been recalculated for the pressures given by formula (6), which follows

$$P_0 = \frac{27{,}600\,(t - 0.04)}{D} - 400 \qquad [6]$$

where

t = wall thickness, in.
D = outside diameter of tube, in.
P_0 = working pressure, psi

Table 2 and Fig. 7 give the results of this analysis. The method of working is slightly different. The rate of heat absorption being fixed, X is assumed as a first trial and K is tabulated. Term Z is solved for and generally will correspond to a

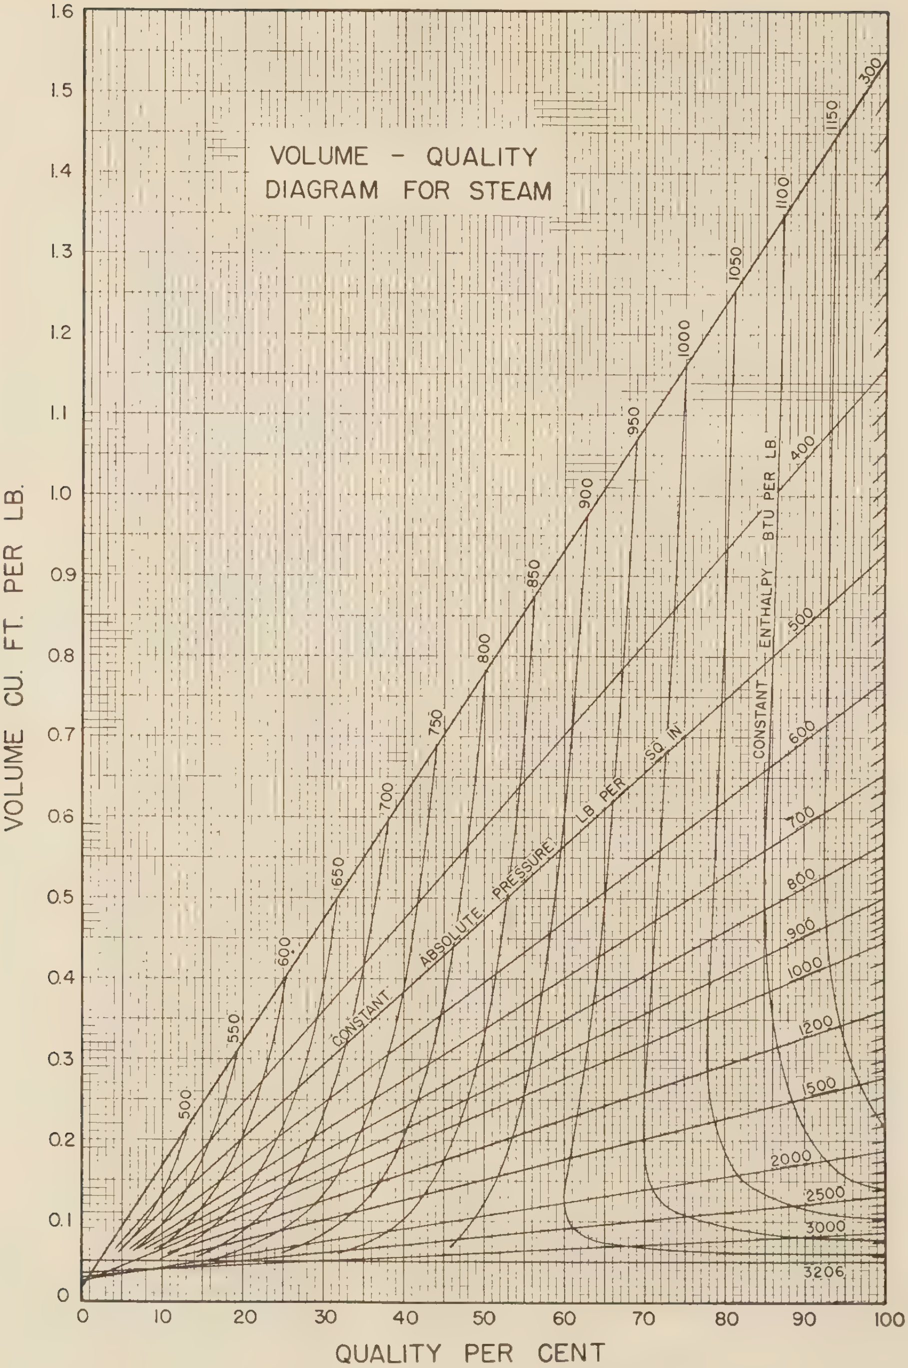

Fig. 5 Volume-Quality Diagram for Steam

different value of X. Term K is then reworked for a new assumed value of X and, as a rule, the second trial will be found exact enough.

Example 3. A problem of interest is the calculation of the circulation characteristic if one downcomer were removed. The results are given in Table 3 and Fig. 6 for the case of uniform heat absorption for 2200 lb.

Analysis of More Complicated Circuits

The analysis of more complicated circuits may be attempted as long as the circuits can be handled by the use of the continuity equation. The general method is to resolve all changes of section by means of area and density relationships into functions of outlet velocity and density. The proper densities to assume might be troublesome on the evaporating side were it not for the following: There are no section changes as a rule inside the furnace, which means that the density leaving the furnace is the same as that leaving the circuit. This being so, only one acceleration loss has to be computed.

Assuming, however, that the circuit consists of a number of

parallel tubes not heated with the same intensity, the analysis becomes intricate. A way to overcome this partially is to consider that, if the riser circuits were connected to a downcomer of low velocity, each circuit would produce an equilibrium quality exactly given by the simple analysis. From this point, by assuming velocities in the downcomers sufficient to produce considerable pressure drop, the qualitative behavior of the less strongly heated circuits can be predicted. In certain cases reversal of circulation or even no circulation is indicated (2, 5). The cause and the cure for such conditions reside in the downcomer part of the circuit. The analysis, however, is straightforward, although beyond the scope of the present paper.

The authors feel assured that if the method here presented will stand the test of discussion and experimental results, the intelligent analysis of natural-circulation problems by the use of models is a possibility.

Appendix 1

Mean Density in a Uniformly Heated Tube

The cumulative weight of steam generated per unit time up to any point l from the inlet is equal to kl, where k is the rate of heat absorption per foot of tube divided by h_{fg}. The quality of the mixture X is therefore equal to (kl/m) where m is the rate of total flow in the tube. At point l, the specific volume is therefore equal to

$$v_{fg}\,(kl/m) + v_f$$

The density at l is the reciprocal of this.

The weight dw of a unit area of height dl is equal to

$$\frac{dl}{v_{fg}\,(kl/m) + v_f}$$

The integral of this between l and 0 is

$$\frac{1}{(k/m)v_{fg}} \log_e \frac{v_f + (kl/m)v_{fg}}{v_f}$$

Dividing this by the length of the tube, and substituting the quality at the outlet for (kl/m), the mean density d_{22} in the tube in terms of the outlet quality X is

$$d_{22} = \frac{2.3}{Xv_{fg}} \log_{10} \left(\frac{d_1}{d_2}\right)$$

Appendix 2

Friction Loss in a Uniformly Heated Tube

If dp is that part of the pressure drop across a length dl, which is due to friction

$$dp = \frac{4fV^2ddl}{2gD} = C'V^2ddl$$

where V is velocity and d density at point l. This can be integrated if V and d can be put in terms of l. This is readily done

$$V = \frac{V_0\,d_0}{d}$$

where V_0 and d_0 are the entering velocity and density, respectively.

$$dp = C' \frac{V_0^2 d_0^2}{d^2} d\, dl = C'' \frac{dl}{d} = C'' v dl$$

where v is the specific volume at point l. Again

$$v = v_{fg} (kl/m) + v_f$$

giving $$dp = [C'' v_{fg} (kl/m) + v_f]\, dl$$

which integrated between l and 0 gives

$$p = C'' v_{fg} (kl^2/2m) + C'' v_f l$$

$$= C'' l \left[\frac{(v_{fg}X) + 2v_f}{2}\right]$$

$$= \frac{4fl}{2gD} \cdot V_0^2 d_0^2 \left[\frac{(Xv_{fg}) + 2v_f}{2}\right]$$

$$= \frac{4fl}{2gD} \cdot V_2^2 d_2^2 \left[\frac{(Xv_{fg}) + 2v_f}{2}\right]$$

in which the bracketed expression is the arithmetic mean of the inlet and outlet specific volume and may be written

$$\left(\frac{1}{d_1} + \frac{1}{d_2}\right) \div 2 = \frac{d_2 + d_1}{2d_1 d_2}$$

$$p = \frac{4fl}{2gD} \cdot V_2^2 d_2 \left(\frac{d_2 + d_1}{2d_1}\right)$$

as a head in terms of d_2 is equal to

$$\frac{4fl}{2gD} V_2^2 \left(\frac{d_2 + d_1}{2d_1}\right)$$

Appendix 3

The ability to predict whether a given circuit, operating at a certain rate of heat absorption, will pass through the circulation maximum is of some interest.

The method of ascertaining this readily will be given for the case of principal absorption at the bottom of the circuit.

By use of the continuity equation we may rewrite Equation [3] in terms of downcomer velocity as

$$V_1 = \frac{C_1(R - 1)^{1/2}}{(\beta R^2 + \alpha R)^{1/2}}$$

where

C_1 = constant, involving l, g, etc.

$R = \dfrac{d_1}{d_2}$

α = Σ resistance coefficients of $\dfrac{d_2}{d_1}$ in Equation [3]

β = Σ remainder of resistance term in Equation [3]

A maximum of V_1 results when

$$\frac{dV_1}{dR} = 0$$

After carrying out the necessary differentiation, it is found that V_1 has its maximum when

$$R = 1 + \sqrt{1 + \alpha/\beta} \qquad [7]$$

Two special cases are of interest.

When the downcomer resistance is negligible, the maximum velocity will occur when the density on the heated leg is one half the density of solid water. When the riser resistance is negligible the circuit will burn out before a maximum velocity is reached.

To locate the point of maximum circulation solve Equation [7] for R or $\dfrac{d_1}{d_2}$. This gives X, the exit quality. Having X, solve for the heat absorption by the method of the text.

Discussion

N. Artsay.[5] My sincere commendation of this excellent paper may be best expressed by the suggestion of several changes which would make the proposed method of wider application. The method is an improvement over the current one in the easy way in which circulation data at various loads of the furnace may be obtained, by plotting quality and other data versus heat absorption and reading the curves back for various loads. However, for a boiler designer who has to do the work of checking circulation against certain criteria, the method must be extended.

(*a*) A coefficient C_1^2, added to the kinetic loss on the steaming side to take into account heavy losses in the fewer riser connections, i.e., side furnace waterwalls, for example.

(*b*) Most of the furnace walls are designed to be supplied from a common downcomer system and, since there is a marked difference in circulation rate per tube, amounting roughly to 25 to 30 per cent between the freely discharging front or rear walls and side walls discharging through a limited number of riser connections, Equation [3] of the paper and its derivatives become inapplicable. The resistance in a practicable downcomer distribution system is quite large and greater by far than the resistance in the wall tubes; hence the amount of water drawn by each waterwall of different size and construction depends substantially upon the total circulation in waterwalls. There are many furnaces in which one of the walls discharges into the lower drum of the unit, complicating the problem yet further. However, it is quite possible to use the method for the several waterwalls as follows:

Allow a set of reduced values l_1 of l to equal the effective height of the circuits and draw curves of V_1 versus heat absorption for every wall; then, according to actual heat absorption, check the valid points of V_1 versus l_1 and draw curves of total water to each wall versus l_1 and the total water of the walls. The intersection of the last curve with the flow in the downcomer system, corresponding to resistance equal to l_1, will give the correct solution for the total flow of circulating water and, knowing l_1, the correct values of circulation.

(*c*) The authors will find that referring all formulation to the inlet velocity into waterwall tubes and to the density of hot

[5] Foster Wheeler Corporation, New York, N. Y.

water will simplify the calculations, and avoid also the unfortunate picture in which the "effective head as the driving force," Equation [2], may be greater than the height of the circuit.

(*d*) The effect of entrainment of steam bubbles in the downcomer system which is quite usual has to be taken into account in a real nonacademic circulation check. With the method offered, it is possible to take this condition into account by reducing the effective circulation head 1 in proportion to water content in the mixture going into downcomers. As a variation a few sets of curves for functions Z and Z_1 with say 3, 5, 10 per cent steam by volume in the downcomers may be prepared.

Looking at the problem of circulation in general, the following is quite noticeable:

The cases, in which the amount of total circulation is insufficient, are extremely few, while the cases of poor distribution of the produced flow are quite frequent. Hence, every effort should be made to ascertain and evaluate the causes of uneven distribution of water between the parallel heated circuits and the effect of uneven distribution of heat absorption between them, which is quite a study in itself.

There is another question of equal importance. Just what is the safe criterion for average circulation in a waterwall and for each tube individually?

E. F. LEIB.[6] The problem, as conceived by the authors, is to establish the circulation characteristics of a circuit for which all dimensions and the rate of heat absorption are given, while the problem of circulation usually appears in the following form: The layout of the furnace and the steam output are given; these determine the number, diameter, and length of all tubes in the furnace, the required heat supply, the kind of the individual resistances, and the heat-absorption rate per unit of heating surface. Thus, the only quantities which may still be disposed of are number and diameter of the unheated downcomer tubes. The problem, therefore, consists in determining the two latter quantities.

There are four points which must be considered in solving the problem:

1 The stability of flow in the steaming tube.
2 The steam generation due to self-steaming.
3 The location of the saturation point.
4 The steam flashing due to pressure reduction in the downcomer.

Points 2 and 3 are important for medium- and low-pressure boilers, while point 4 is of interest in forced-circulation boilers particularly. Formulated in this manner, the equilibrium equation for the circulation problem permits a straightforward solution as outlined in the following:

The assumptions are the same as those made by the authors, with their assumption 5 discarded later in this analysis. For the sake of simplicity, it may be assumed that only two different tube diameters occur as follows:

Radius of the m riser tubes and all other connections: R', ft; flow G', lb per sec.

Radius of the n unheated downcomer tubes: R'', ft; flow G'', lb per sec.

Then we have for the total flow in the circuit

$$G = m\,G' = n\,G''$$

which gives

$$G'' = \frac{m}{n}\,G' = \mu\,G' \;\ldots\ldots\ldots\ldots\ldots\ldots [8]$$

The pressure difference between given points in the circuit consists of the difference in static head ΔP_s and the individual pressure losses, ΔP_L (entrance, acceleration, friction, exit). This pressure difference may be written separately for the two sections of the circuit with tube radius R' and R'', respectively, as follows

$$\Delta P' = \Delta P_s' + \Sigma\,\Delta P_L' \text{ (riser)} \ldots\ldots\ldots\ldots [9]$$

$$\Delta P'' = \Delta P_s'' - \Sigma\,\Delta P_L'' \text{ (downcomer)} \ldots\ldots\ldots [10]$$

The authors have shown how these quantities may be represented by the flow rate, tube radius, tube length (L), heat-absorption rate (Q), and the thermal properties of the steam and water. For these thermal properties we use the symbol θ, comprising any quantity obtainable from the steam tables, such as specific volume and enthalpy of water and steam, or the heat of evaporation. We then write for Equations [9] and [10] of this discussion

$$\Delta P' = f_1(G', R', L, Q, \theta) \ldots\ldots\ldots\ldots [11]$$

$$\Delta P'' = f_2(G'', R'', L, \theta) \ldots\ldots\ldots\ldots\ldots [12]$$

The exact determination of the functions f_1 and f_2 has to be done in accordance with the authors' formulas for the individual losses as they occur for the particular circuit under consideration.

Equilibrium requires that

$$\Delta P' = \Delta P''$$

or

$$f_1(G', R', L, Q, \theta) = f_2(G'', R'', L, \theta) \ldots\ldots\ldots [13]$$

It is possible to replace the flow rate by the top-dryness fraction x_0 by means of the relation for the total amount of heat supplied to each tube per unit time

$$Q = G'x_0h_{fg} \text{ Btu per sec} \ldots\ldots\ldots\ldots [14]$$

We further introduce the diameter ratio

$$s = \frac{R''}{R'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [15]$$

Substituting from Equations [8, 14, 15], Equation [13] can be written

$$f_1(x_0, R', L, Q, \theta) = f_2(\mu, s, x_0, R', L, Q, \theta) \ldots\ldots [16]$$

Exact calculation shows that the function f_2 has the form

$$f_2 = \mu^2\,\frac{C_1s + C_2(L/R')}{s^5} \times f_3(x_0, R', L, Q, \theta) \ldots\ldots [17]$$

Introducing Equation [17] into [16] and solving for μ^2 yields

$$\mu^2 = \frac{s^5}{C_1s + C_2L/R'} \times F_1(x_0, R', L, Q, \theta) \ldots\ldots [18]$$

where F_1 has been written for f_1/f_3, both functions having the same argument. In this equation, the constants C_1 and C_2 and the quantities R', L, Q, θ are given by the design data. As soon as the dryness fraction x_0 is given, Equation [18] gives pairs of values μ, s which all comply with the equilibrium condition of Equation [13]. Then, using Equations [8] and [15], we obtain from Equation [18] co-ordinated values for the radius and the number of downcomer tubes, which give the desired flow condition. The next objective is, therefore, the determination of x_0.

A maximum permissible value of x_0 is obtained from the postulate that the flow in the steaming (riser) tube must be stable. The calculation of stability conditions has been explained in detail by the writer.[7] The procedure is shown for a particular

[7] "A Study of Circulation in High-Pressure Boilers and Water-Cooled Furnaces," by John Van Brunt, Trans. A.S.M.E., vol. 63, May, 1941, pp. 339–343; discussion by E. F. Leib, pp. 345–347.

example in Fig. 8 of this discussion. First set up the equation for the pressure through the steaming tube between both headers

$$\Delta P = \Delta P_s \pm \Sigma \Delta P_L$$

The plus sign holds for upward-directed flow (right branch of curve), and the minus sign holds for downward-directed flow (left branch of curve). Both equations can be represented in terms of the following variables

$$\text{Riser } (+ \text{ sign}) \quad \Delta P = f_4(x_0^+, R', L, Q, \theta) \ldots\ldots [19]$$

$$\text{Downcomer } (- \text{ sign}) \quad \Delta P = f_5(x_0^-, R', L, Q, \theta) \ldots\ldots [20]$$

Then find the maximum of the left branch by differentiating Equation [20] with respect to x_0^- and solving for x_0^- (point A). Substitute this value x_0^- into Equation [20] to obtain the pertaining pressure (point B). Substitute this pressure into Equation [19] and solve for x_0^+ to obtain the pertaining dryness fraction and flow rate (point C). Each flow condition to the right of C is stable. We will, therefore, select a value of x_0 slightly smaller than x_0^+ and introduce this value into Equation [18]. Then, all variables in the function F_1 are known.

As the liquid moves upward in the steaming tube, the pressure on the liquid is continuously reduced, partly due to a decrease in static pressure and partly due to pressure loss by friction. Fig. 9 of this discussion shows that, when the pressure decreases, the enthalpy of the saturated liquid decreases, too. Thus, a certain amount of heat is liberated for the generation of steam (change of state I → III in Fig. 9). At medium and lower pressures, this additional steam generation without heat supply, which is referred to as "self-steaming," is appreciable and has to be considered in order to obtain a correct circulation analysis. Consider the increase in steam content dx over the tube length dl. The mean steam content in this tube section is x. Then, the amount of liquid flowing in 1 sec through this section is $G'(1 - x)$. The pressure decreases in the tube section dl by the amount dp. The accompanying decrease in enthalpy is dh' which produces the steam quantity

$$dM_1 = -\frac{(1 - x)G'}{h_{fg}} dh' \ldots\ldots [21]$$

The simultaneous evaporation due to the heat supply is

$$dM_2 = \frac{Q}{h_{fg}} \frac{dl}{L} \ldots\ldots [22]$$

with L as total tube length and Q the heat supplied over this total length. Thus, the evaporation in the tube section dl is

$$G'dx = dM_1 + dM_2 = \frac{1}{h_{fg}} \left[\frac{Q}{L} dl - (1 - x)G' \frac{dh'}{dp} dp \right] \quad [23]$$

where dh'/dp is the change of enthalpy of saturated water for the pressure change dp and can be taken from the steam tables. Equation [23] can be written

$$dx = \left[\frac{Q}{G'L} - (1 - x) \frac{dh'}{dp} \cdot \frac{dp}{dl} \right] \frac{dl}{h_{fg}} \ldots\ldots [24]$$

We have now to find dp/dl, which is the pressure reduction over the tube section dl. The reduction of the static head contributes

$$-dp_s = \frac{dl}{v} = \frac{dl}{v' + x(v'' - v')} = \frac{1}{1 + Bx} \cdot \frac{dl}{v'}$$

and the friction loss contributes

$$-dp_f = \frac{fG'^2}{g\pi^2 R'^5} [v' + x(v'' - v')]dl = \frac{fG'^2 v'}{g\pi^2 R'^5} (1 + Bx)\, dl$$

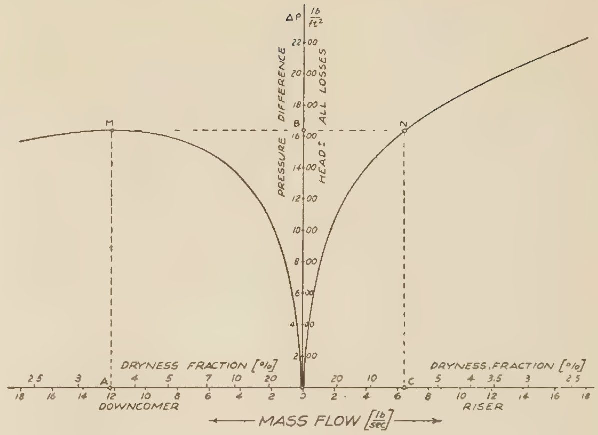

Fig. 8 Stability Curve

(For 1350 psi pressure; 3-in. tube, 50 ft long; 72,000 Btu per sq ft per hr heat absorption.)

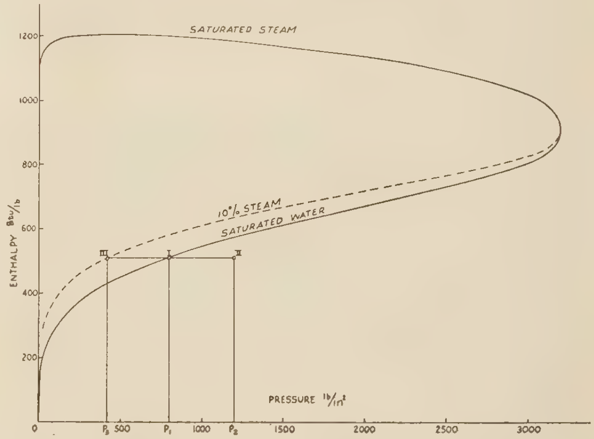

Fig. 9 Pressure-Enthalpy Diagram for Saturated H_2O

where v' = specific volume of saturated water
v'' = specific volume of saturated steam $\Big\} B = \dfrac{v'' - v'}{v'}$

By adding dp_s and dp_f, we obtain

$$-\frac{dp}{dl} = \frac{1/v'}{1 + Bx} + \frac{fG'^2 v'}{g\pi^2 R'^5} (1 + Bx) \ldots\ldots [25]$$

By substituting Equation [25] into [24], and by separating the variables, we have the differential equation for the local dryness fraction in the tube

$$\frac{dx}{\dfrac{Q}{G'L} + \dfrac{1 - x}{v'} \dfrac{dh'}{dp} \left[\dfrac{1}{1 + Bx} + \dfrac{fG'^2 v'^2}{g\pi^2 R'^5} (1 + Bx) \right]} = \frac{1}{h_{fg}} dl \ldots\ldots [26]$$

Fig. 10 of this discussion shows the result of the integration of Equation [26] for one particular example. In the two cases shown, the contribution of self-steaming to the total steam generation is 7 per cent and 15 per cent, respectively, an amount which cannot be neglected. Since, as a satisfactory approximation, the total steam generation can be represented by a straight line in Fig. [10] of this discussion, the local dryness fraction can be written as

$$x = \frac{zQ}{G'h_{fg}} \cdot \frac{l}{L} \ldots\ldots [27]$$

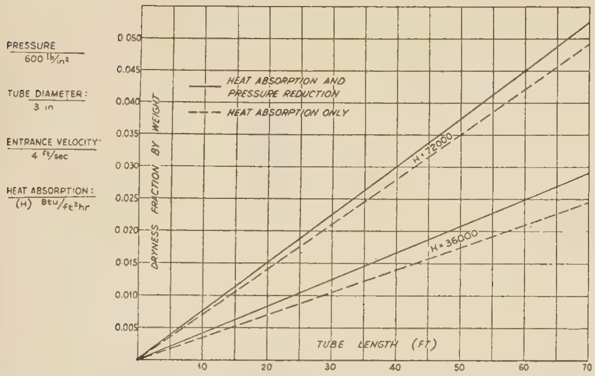

FIG. 10 EFFECT OF PRESSURE DROP ON STEAM GENERATION

where the value of $z > 1$ is found by integrating Equation [26]. Thus, the quantity of steam actually generated equals that which is obtained if the heat zQ instead of the heat Q were supplied to the tube.

The pressure drop through the tube is obtained by substituting x from Equation [27] into Equation [25] and integrating. The result is

$$\Delta P = \frac{G'h_{fg}L}{zQBv'} \ln \left(1 + \frac{zQB}{G'h_{fg}L}\, l\right) + \frac{fG'^2v'}{g\pi^2R'^5}\, l \times \left(1 + \frac{zQB}{G'h_{fg}L} \cdot \frac{l}{2}\right) \ldots\ldots [28]$$

Thus, the pressure drop for a tube with self-steaming equals the pressure drop through a tube without self-steaming to which the heat zQ is supplied instead of Q.

In a circuit like that used for illustration by the authors, the steam-water mixture enters the drum from the end of the steaming tube. The feedwater entering the drum is then at saturation condition corresponding to this pressure. Since the evaporation in the steaming tube starts at a higher pressure, a corresponding amount of sensible heat must be supplied to the feedwater in order to bring it to the saturation condition pertaining to this pressure. Thus, a portion of the heating surface is needed to supply this heat, and the saturation point is not at the bottom of the tube. Of the total tube length L, the portion L'' is available for steam generation, while the portion $(L - L'')$ serves to supply the sensible heat to the water. The pressure drop through the steaming portion is obtained by substituting L'' for l into Equation [28]; then

$$\Delta P = \frac{G'h_{fg}L}{zQBv'} \ln \left(1 + \frac{zQB}{G'h_{fg}} \cdot \frac{L''}{L}\right) + \frac{fG'^2v'L''}{g\pi^2R'^5} \left(1 + \frac{zQB}{2G'h_{fg}} \cdot \frac{L''}{L}\right) \ldots\ldots [29]$$

The sensible heat to be supplied to the feedwater to reach saturation condition at a pressure which surmounts the entrance pressure by ΔP is

$$Q' = G' \frac{dh'}{dp}\, \Delta P \ldots\ldots [30]$$

For uniform heat absorption holds

$$Q' = Q\, \frac{L - L''}{L} \ldots\ldots [31]$$

Equating Equations [30] and [31] and solving for ΔP gives

$$\Delta P = \frac{Q}{G'} \cdot \frac{dp}{dh'} \cdot \frac{L - L''}{L} \ldots\ldots [32]$$

By equating Equations [29] and [32] an equation for the unknown quantity L'' is found. Solving for L'' gives the correct location of the saturation point. At medium and lower pressures, the portion of tube needed to supply the sensible heat is considerable. The pressure-drop calculation in Equation [11] must be carried out with the correct values for those portions of the steaming tube containing the solid water and the steam-water mixture, since the friction loss is very different for both portions. Therefore, the authors' assumption 5 is inaccurate for medium and lower pressures, and their diagrams can be used in this region only with caution.

Finally, the question arises whether a second relationship between the variables μ, s occurring in Equation [18] could be established, such that a single-valued solution for these two variables might be found. Such a relationship can be derived from the postulate that, in case of a sudden increase in load, a maximum of pressure reduction shall be permitted in the system without resulting in steam flashing in the unheated downcomer tubes. Since this condition is exclusively used in the determination of downcomer tubes for forced-circulation boilers, it may only be mentioned here.

W. H. ROWAND.[8] The authors' first assumption that all the steam is made at the bottom of the rising circuit, and the use of the density of the mixture leaving the circuit as the average density, and their second assumption that the average density is the log mean are simplifications for calculation work over the use of some other evaluated average density. While this results in circulating flows which are higher than will actually obtain, the error is not too great so long as the per cent steam by volume leaving the circuit is relatively low, and so long as the velocity of the mixture is high, compared with the relative velocity between the steam and the water. When limiting cases are being considered, however, it is important to evaluate the average density in such a way that it will agree closely with that obtained from actual test data in the field.

It is believed that the term, "per cent steam by volume" leaving a circuit, is a better yardstick for judging the safety of a tube from overheating than steam quality or per cent steam by weight, since it presents a physical picture of the degree to which the tube is being wetted regardless of the pressure.

The authors have reduced the differential head and all friction losses to feet of water corresponding to the density leaving the heated tube. While this procedure is satisfactory for a single simple circuit, it is impractical for multiple circuits where each circuit must not only be balanced within itself but also must be balanced with all the other circuits in the system; this being the usual case in most practical analysis work. It is suggested that a more practical reference base is 62.4-density water.

Table 4 of this discussion gives a comparison between a circulation test conducted recently by the writer's company on an open-pass-type boiler, operating at 1350 psi pressure, and the first method of calculation presented by the authors using the density leaving the circuit as the average density, modified to make it applicable to the many interconnected circuits, and also the method of calculation used by the writer's company for several years. In general, the authors' method results in more optimistic circulation than was actually obtained, and the company's method gives somewhat less circulation that the test results,

[8] Mechanical Engineer, The Babcock & Wilcox Company, New York, N. Y. Jun. A.S.M.E.

TABLE 4 COMPARISON OF CIRCULATION TEST BY B & W WITH AUTHORS' FIRST METHOD OF CALCULATION

		Test results			Authors' method using B. & W. method of balancing			B. & W. Co. method		
Circuit	Steam flow	Circulation	Mixture steam ratio	Steam by volume, per cent	Circulation	Mixture steam ratio	Steam by volume, per cent	Circulation	Mixture steam ratio	Steam by volume, per cent
A	109,800	1,738,000	15.8	48.5	1,610,000	14.7	49.3	1,118,000	10.2	59.0
B	102,800	1,610,000	15.7	48.5	1,988,000	19.4	42.5	1,376,000	13.4	51.7
C	50,000	1,220,000	24.4	36.5	1,657,000	33.1	29.1	1,105,000	22.1	38.2
D	27,300	568,000	20.8	40.5	860,000	31.5	30.5	563,000	20.6	41.0
E	18,600	354,400	19.1	42.5	434,000	23.3	38.0	283,000	15.2	49.0
F	33,500	308,400	9.2	62.0	440,000	13.1	52.3	248,000	7.4	67.2
G	64,800	956,000	14.8	49.3	1,104,000	17.0	45.4	928,000	14.3	50.0
H	17,600	355,000	20.2	41.0	361,000	20.5	40.3	258,000	14.6	49.4
I	78,400	1,210,000	15.4	48.0	1,320,000	16.8	45.6	816,000	10.4	58.3
J	77,700	621,000	8.0	65.5	699,000	9.0	62.5	400,000	5.2	77.0
K	68,200	544,000	8.0	65.5	636,000	9.3	62.0	358,000	5.8	74.5
Total and Average	648,700	9,484,800	14.6	50.0	11,109,000	17.1	46.0	7,453,000	11.5	55.0

which is on the conservative side. The total calculated circulation by the authors' method is 17 per cent above the actual test results, while, by the company's method, it is 20 per cent below.

Authors' Closure

The authors feel that there have not been many papers presented before this Society in which the discussion has done more to enhance the value of the original presentation than in the present instance. On the whole, criticism of the paper itself is minor.

Messrs. Rowand and Artsay believe that the choice of reference densities in terms of the mixture leaving the circuit was unhappy. We are inclined to agree with this reaction, since the choice of reference density is merely a matter of convenience. Having absorbed the principles, which somehow seem better illustrated by the use of exit conditions, there is no great difficulty in changing to a reference density of cold water or, what amounts to the same thing, in working directly with pressure drop. Artsay points out that where there is considerable loss in junction headers the kinetic losses are greater than in the illustrative example. This is easily taken care of by including these losses in the resistance tabulation. His suggestion for taking care of steam in the downcomers by constructing new Z curves is good as an educational exercise. Practically, we know now by experience that steam must be kept out of the downcomers if we are to have good boilers.

The remainder of Artsay's discussion is much to the point although we do not agree with his remark that the use of effective heads, which may be greater than the linear height of the circuit, is unfortunate. The concept of a head in terms of a homogeneous column of fluid is the first simple relationship which must be acquired before even the simplest hydraulic problems can be tackled away from a handbook.

The discussion by Lieb, which deals with the effect of flashing, due to sudden pressure drop on a boiler, is interesting. While clothed with a considerable (to the authors) mathematical treatment, the information presented will be valuable to students of the subject. His criticism of the authors' assumption of constant friction factor is good, and, fortunately, the authors can throw additional light on this subject before concluding.

It is to Rowand that we are most indebted. The paper as presented lacked experimental data to indicate to the engineer, who is interested in the application of novel methods of analysis, the amount of confidence that might be placed in them. Rowand shows in his comparison of actual measurements on a 1350-lb boiler with the calculated results that methods, such as the authors', or modifications thereof, are more than mere exercises. This, however, has been known for some time by a few of the boiler manufacturers. The authors wish to state that the publication of important and previously unpublished experimental results as a discussion of the work of others is a laudable act.

Until the Sherman Creek experiments on heat transfer and friction drop in tubes, in which water was boiling at high pressure, were concluded, we could do no more than assume constant friction factors for such analyses. The use of the data obtained in those experiments will bear out Rowand's contention that such methods fall progressively in error as the percentage of evaporation increases. These data will be published soon in the Transactions and will accommodate Rowand's criticism quantitatively. They will also show that "per cent steam by volume" presents no fundamentally clear technical concept of tube safety.

As to the proper density of the mixture to assume in an actual boiler for the purpose of useful calculations, it now appears from Rowand's comparison that the use of the logarithmic-mean density, with friction factors as indicated by the Sherman Creek data, may be expected to give results worthy of a better designation than mere estimates.

Turbines for Power Generation From Industrial-Process Gases

By JOHN GOLDSBURY[1] and J. R. HENDERSON,[2] LYNN, MASS.

This paper presents a discussion of the fields of application for turbines operated by industrial-process gases and natural gases, examples of the mechanical details of actual turbines which have been built for such applications, a simple method for calculating the energy available in a pure or a compound gas for specific operating conditions, and the properties of various gases for use in such calculations. After a study of the available data on gas properties, the authors have selected for the working curves those which were considered to be most authentic.

Nomenclature

The following nomenclature is used in this paper:

a = fractional part by volume (of a component in a mixture)
b = fractional part by weight (of a component in a mixture)
c_p = constant-pressure specific heat, Btu per deg F per lb
c_v = constant-volume specific heat, Btu per deg F per lb
E = available energy of isentropic expansion or compression, Btu per lb
e = turbine efficiency, dimensionless
k = exponent of isentropic expansion or compression
M = molecular weight of a pure gas or equivalent molecular weight of a gas mixture
m = molecular weight of a component in a gas mixture
p = pressure, psi abs
Q = gas flow, cfm at 60 F and 14.7 psi abs (i.e., free gas)
R = gas constant = pv/T
T = temperature, deg F abs, or deg Rankine
v = specific volume, cu ft per lb
$(\ )_0$ refers to condition of gas at zero pressure
[a]$(\ )_1$ refers to condition of gas before expansion or compression
[a]$(\ )_2$ refers to condition of gas after expansion or compression
$(\ )_c$ refers to condition of gas at critical point
$(\ )_m$ refers to mean value between $(\ )_1$ and $(\ )_2$

Field of Usefulness for Industrial-Process-Gas Turbines

Many modern industrial processes involve the production or use of gases or vapors under pressure. It is apparent that certain desirable reactions take place more effectively under pressures above atmosphere. In some cases, the gain in the quality or quantity of the product seems to be well worth the cost of air or gas compression. In the case of natural gas, the compression, as well as the gas itself, is contributed by nature. In any case, when a continuous flow of gas is available under pressure above atmosphere, it will be well to consider whether advantage cannot be derived from expanding the gas through an elastic-fluid turbine.

This term "elastic-fluid turbine" is used to denote the general class of turbines which are operated by the expansion of any gas or vapor. The general features are the same as those of the steam turbine, but the dimensions, materials, and design details will be determined by the particular elastic fluid used, as well as by the pressures and temperatures involved.

Not only may it be found that the use of a turbine will improve some established processes or increase the economy of operation, but the possible advantages of a turbine may turn the balance in favor of new processes being considered.

In some cases, certain difficulties may arise, such as corrosiveness of the gas, presence of liquid, gummy, or solid particles carried by the gas, or arising from physical or chemical changes, etc. If, however, the advantage of using the gas in a turbine is great, ways of overcoming these difficulties can frequently be found.

In general, the justification for a turbine would be the power which it could produce, but an increasing number of processes are being considered in which the advantage of the turbine is the reduction in gas temperature due to the energy absorbed by the turbine. At least one such application has been made and several others have been considered.

Application in Petroleum-Refining Processes

The most important development so far in the use of turbines, driven by industrial-process gases other than steam, is found in connection with certain catalytic petroleum-refining processes. In these processes carbon is deposited on the catalyst. The carbon must be burned off and the catalyst regenerated at frequent intervals. In several of these processes, it is apparently most effective and economical to burn off the carbon under pressure. In some cases, the pressure is as high as 300 psi, and much higher pressures have been proposed. Several catalyst retorts are frequently used so that one or more can be undergoing the regeneration processes continuously. The maximum regeneration temperature is controlled either by tubes through which a coolant is passed, or by recirculation of some of the products of combustion which have passed through a waste-heat boiler, or by other suitable means. There is, then, a steady flow of these products of combustion or flue gas which is of no further use to the process.

The heat could, of course, be partially recovered in a waste-heat boiler or other type of heat exchanger, but the pressure potential would be largely wasted. The pressure potential can be utilized and a large portion of the heat removed by passing the gas through a turbine.

Fig. 1 shows a 3500-hp flue-gas turbine on the test floor. A cross-sectional view through this turbine is shown in Fig. 2. The following description indicates some of the problems which must be considered in connection with such turbines.

With some grades of process charge, sulphur will be deposited on the catalyst. This will appear as SO_2 in the flue gas. In order to avoid corrosion from this, as well as from any other possible corrosive component in the gas, it was decided to make the

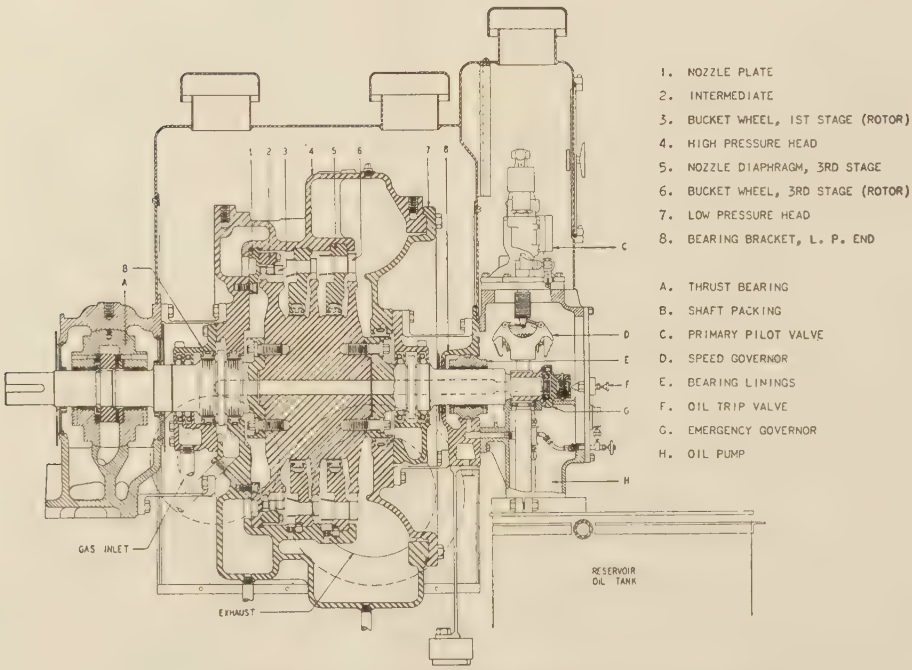

Fig. 2 Cross-Sectional View Through 3500-Hp Flue-Gas Turbine

rotor, buckets, nozzles, and some other parts of this particular turbine of a high grade of stainless steel, while a low-alloy steel was used for the casing parts. Valve trim was of stellite, interior packings were of a special cast iron, and outer shaft packings of carbon. Recent tests have indicated that less expensive and more easily workable materials will probably be suitable for many of the parts when the corrosive components of the gas are only SO_2 and water.

As further protection against corrosion it is planned in so far as possible to operate the turbine only at exhaust temperatures well above the condensation points of any acids likely to be present in the gas. When the turbine is to be shut down for any extended period, hot dry air or neutral gas will be blown through the casing, packing glands, valves, etc., to purge out all traces of the gas, and precautions will be taken to prevent any gas from leaking into the turbine during such periods.

Although no solid materials in appreciable quantities are expected to be entrained with the gas, provision has been made for the admission of air to the shaft-packing glands, if that is necessary to prevent such material from settling in the packings. Space has been provided for assembly of special interstage packings which can also be sealed with air if experience indicates the need.

Because of the large coefficient of thermal expansion of the stainless-steel rotor, it was necessary to use particular care in designing packing and other clearances to prevent any possibility of rubbing, even under large and rapid changes in load or operating conditions. In general, the turbine was designed for simplicity and ruggedness rather than highest efficiency. The first of the three stages is velocity-compounded with two rotating bucket rows and with circular nozzle ports. Maximum turbine efficiency, together, doubtless, with other refinements contributing to plant economy, can come later, when the experience necessary for determining the best over-all arrangement is available.

Fig. 3 shows the control arrangement for this turbine. The mechanism is such that speed can be held constant at any set value within the setting range of the governor, in this particular case, from 2800 to 4000 rpm. The speed governor *a* controls a single admission valve *b* through an oil operating cylinder, not shown. In order to assist the speed governor in holding constant speed in spite of large variations in gas-main pressure, a constant-pressure governor *c* is used to control the pressure ahead of the speed-governing valve. The pressure governor controls a valve *d* which by-passes excess gas around the turbine. Fluid-restoring links, not shown in the diagram, permit very close net speed and pressure regulation, combined with instantaneous regulation which is broad enough to be stable.

This particular turbine was designed to be installed out of doors, and the sheet-metal lagging, oil-tank cover, etc., were consequently made weatherproof.

Details of 885-Hp Flue-Gas Turbine

In Fig. 4 is shown the control diagram for another flue-gas turbine of 885 hp capacity. In this case, a 1460-hp steam turbine is coupled to the same shaft for starting and for supplementing the gas-turbine power.

Referring to the diagram, it will be seen that both turbine admission valves, *b* and *d*, are controlled by one speed governor *a*, through oil relays. The linkage is arranged in such a manner that the gas-turbine valve *d* opens first, the steam-turbine valve *b* then opening to whatever extent is necessary to make up the difference between the load required and the power which can be obtained from the gas turbine under the particular conditions considered. The steam valve has an overtravel in the closed position, so that it does not lift above its seat until the gas valve is nearly wide open.

Although there is only one speed governor, a separate emergency overspeed governor is provided on each turbine, to prevent runaway of either turbine in case of loss of its load. The emergency governor *f* on the gas turbine will dump the oil pressure from the gas-admission-valve cylinder *e* only, while the emergency governor *g* on the steam turbine will dump the oil pressure from both the gas *e* and steam *c* admission-valve cylinders, to cover the case of complete loss of load on the compressor.

The governing mechanism also includes a device, not shown in Fig. 4, to admit a small steam flow to the steam turbine to carry away the heat resulting from windage of the buckets, rotating idly while the compressor is being driven by the gas turbine. Steam is also supplied to the shaft seals of the gas turbine, to prevent leakage of gas.

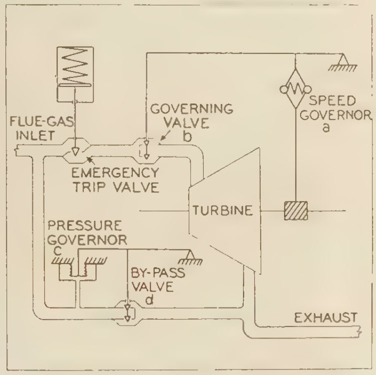

Fig. 3 Control Diagram for 3500-Hp Flue-Gas Turbine

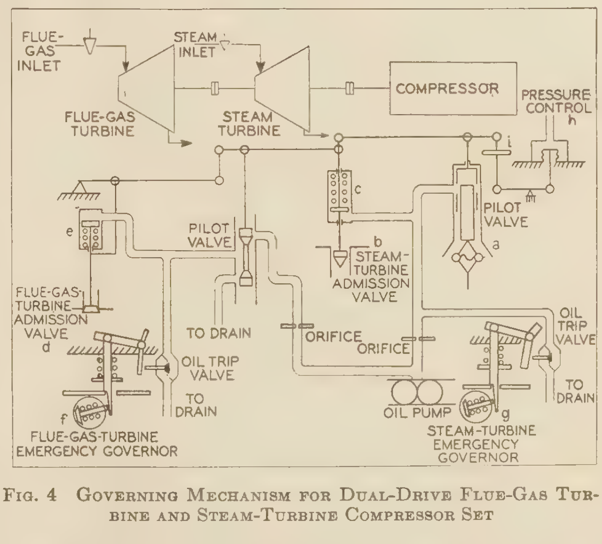

Fig. 4 Governing Mechanism for Dual-Drive Flue-Gas Turbine and Steam-Turbine Compressor Set

The speed setting of the governor *a* can be regulated either automatically by the pressure control *h* or manually by the handwheel *i*.

Natural-Gas Industry Offers Possibilities for Turbines

Another large potential field for power from expansion of gas through turbines is the natural-gas industry. It has been calculated that the total work which might theoretically be thus extracted from the annual production of natural gas in the United

States is of the order of 1,750,000,000 kwhr.[3] Numerous very small turbines of standard steam designs are being operated by natural gas and used to drive pumps and other apparatus. However, there are undoubtedly many cases where no power is derived from expansion of the gas, but where the pressure drop from the well to the point of use is much greater than is really needed to overcome friction losses in pipes of reasonable size.

In the repressuring process of liquid extraction from natural gas, well pressures run from 1500 to 3000 or more psi, while the pressure in the absorption tower is usually from 1000 to 1500 psi. Since the amount of liquid extracted increases with decrease in temperature, any power extracted by passing the gas through a turbine would contribute also to the yield. The turbine could be designed to separate out a large portion of the liquid from the gas by centrifugal force, and might thereby replace one or more of the extraction devices normally used. Taking a case where 50,000,000 cu ft of free gas per day are processed with a gas-main pressure of 2000 psi, dropping down to 1000 psi at the absorption towers, if we assume a temperature of 100 F at the main and a net pressure ratio of 1.8 for the turbine after allowing for pipe losses, the net power obtainable will be approximately 650 hp.

Problems Entailed by Low Gas Temperatures and Fire Hazard

The temperature of natural hydrocarbon gas, as it issues from the wells, is very low compared with that of combustion gases. It is frequently less than 120 F. When such gas is expanded through a turbine, the temperature at the turbine outlet may be below freezing. This not only requires the use of materials which retain their ductility and strength at such low temperatures, but also introduces a possible difficulty from ice formation. If considered advisable, moisture, hydrates, and even carbon dioxide can be removed from the gas before it enters the turbine.

In one natural-gas application, where turbines were used to drive electric generators, special precautions were taken to avoid danger from ignition of gas which might leak from the packings. One of these precautions was the use of a fire wall between the turbine and the generator. Another was the use of beryllium copper for the trigger of the emergency overspeed governor in order to prevent sparks when the emergency governor bolt strikes the trigger. An explosion-proof speed-synchronizing control motor is also used.

[3] Based on 1939 production of 2,435,000,000,000 cu ft; *World Almanac*, 1941.

There are, of course, other processes than those mentioned in which gases are expanded through turbines, but it would seem probable that very much more can profitably be done along these lines.

Methods of Deriving Turbine Output

In order to determine in any particular case whether it will be profitable to expand a gas through a turbine, a calculation or estimate must be made of the power obtainable. The nomograph in Fig. 5 can be used for rough work to obtain quickly approximate outputs from given quantities of gases at various temperatures and pressure ratios. A formulation has been introduced whereby turbine efficiency is included on a basis which gives approximately the correct characteristic with respect to size, but of necessity many variables cannot be evaluated in such a chart. The reduced size of the chart, because of space restrictions, in itself precludes accurate results, but for very rough approximations it may be found useful.

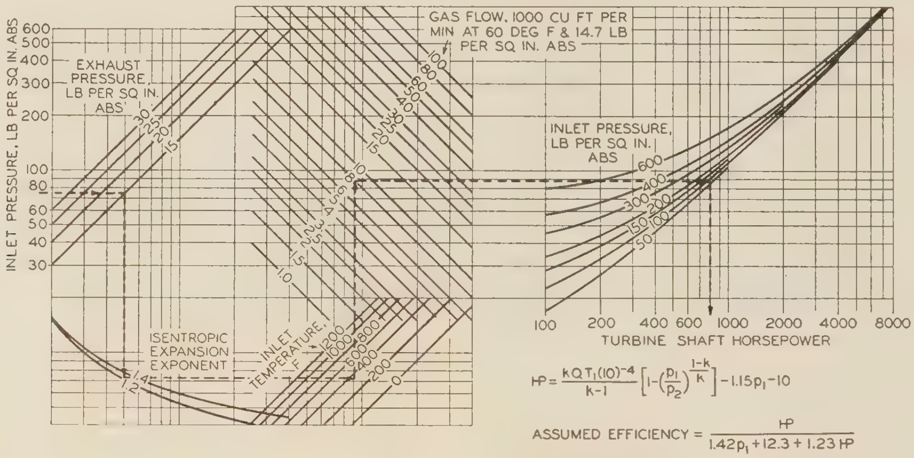

Fig. 5 Approximate Gas-Turbine Performance

An example of the derivation of turbine output by the use of the nomograph in Fig. 5 is given in the appendix. For comparison the same example is also worked out by the method to be described.

For more accurate determinations something must be known of the properties of the gas and suitable methods must be used to calculate the available expansion energy. Although much work has been done on measurement of the thermodynamic properties of the common gases, the reports of many of these measurements are scattered through the literature. A great amount of work is necessary to assemble these data and to convert the various quantities to common English units. For the convenience of engineers who wish to use these properties, the p-v-T relationships of several common gases are given herewith. In general, the complete range of temperatures for which data were found is given, and, in several cases, extrapolations have been made by means of the Beattie-Bridgman[4] equation of state or by other means.

The range of pressures for which data were given was usually more than adequate for normal use. These p-v-T relations are presented on charts which are necessarily of restricted size, but determinations from them will be accurate enough for most purposes.

[4] Extrapolations of some of the p-v-T data which follow have been made by means of the Beattie-Bridgman formula as given in Bibliography reference (11).

Power Outputs for Superheated-Gas Expansions

A method for obtaining quite accurately turbine inputs or theoretical power outputs for superheated-gas expansions will be described. This method has been found very convenient for such calculations. For a pure gas, the accuracy of the results depends chiefly upon the accuracy of the available data on the properties of the gas, and upon the accuracy of the secondary data, derived from the basic data. In calculations with superheated steam through a very wide range of initial pressures, initial temperatures, and pressure ratios, the inaccuracies due to the approximations of the method itself are seldom as great as 0.5 per cent when compared on the basis of available energy per pound with those derived directly from the Keenan and Keyes tables (1).[5] Since both the basic and derived steam properties are also taken from these tables and from the accompanying curves, the comparison was between two methods of deriving available energies from these properties.

The method being described is based on the assumption that, if the initial specific volume can be found, and if a suitable mean value of isentropic exponent can be obtained, the available energy from the expansion of 1 lb of any gas from given initial pressure and temperature to a given final pressure can be determined from the formula

$$E = \frac{144}{778} p_1 v_1 \frac{k}{k-1}\left[1 - \left(\frac{p_1}{p_2}\right)^{\frac{1-k}{k}}\right] \quad \text{[1]}$$

where E = available energy, Btu per lb of gas
p_1 = initial pressure, psi abs
p_2 = final pressure, psi abs
v_1 = initial specific volume, cu ft per lb
k = mean isentropic-expansion exponent

If the gas flow is given in cubic feet per minute of free gas, (60 F, 14.7 psi abs) the turbine output in horsepower is

$$\frac{Q \times 60 \times M \times E \times e}{2545 \times 380} = 6.2(10)^{-5}\, QMEe \quad \text{[2]}$$

where Q = gas flow
M = molecular weight
e = turbine efficiency, which must be assumed or obtained from the manufacturers

For a perfect gas, k is constant throughout the expansion, and the formula is exact. Also, for a perfect gas, $p_1v_1 = RT_1$. With temperature T_1, in degrees Rankine or Fahrenheit absolute, and p and v in the units given, $R = \dfrac{10.72}{M}$. With all actual gases pv/T is not constant. Curves of pv/T plotted against temperature at different pressures are shown in Figs. 6 to 14, inclusive, for several common gases. References are given in the Bibliography to the sources of the data for each chart.

Curves of $E/(p_1v_1)$ plotted against p_1/p_2 for various values of k are shown in Fig. 15. These curves may also be used for determining the energy of isentropic compression by using the curves above $k = 1$. In this case Equation [1] becomes

$$E = \frac{144}{778} p_1 v_1 \frac{k}{k-1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1\right] \quad \text{[1a]}$$

Enlarged curves for greater accuracy can readily be prepared from calculations using Equations [1] and [1a]. Plotting $E/(p_1v_1)$ against k for constant values of p_1/p_2 facilitates accurate interpolation, but many curves are required.

Curves of k versus T for constant values of p are shown in Figs. 16 to 18, inclusive, for three gases. The zero-pressure curves are calculated from the new values of c_{p0} derived from spectroscopic investigations. The formula used for k_0 was

$$k_0 = \frac{c_{p0}}{c_{p0} - \dfrac{1.985}{M}} = \frac{c_{p0}}{c_{v0}} \quad \text{[3]}$$

Values of k at pressures other than zero were derived from the formula

$$k = -\frac{v}{p}\left(\frac{\partial p}{\partial v}\right)_T \frac{c_p}{c_v} \quad \text{[4]}$$

where

$$c_p = c_{p0} - \int T\left(\frac{\partial^2 v}{\partial T^2}\right)_p dp \quad \text{[5]}$$

and

$$c_v = c_p + T\frac{(\partial v/\partial T)_p^{\,2}}{(\partial v/\partial p)_T} \quad \text{[6]}$$

Calculations of k using this formula are quite laborious. The derivatives were obtained by taking the ratios of differences at small intervals. The consistency of these differences was improved by taking second differences, and drawing smooth curves through them, then calculating new primary differences from the smoothed second differences. Fortunately, except at large pressure ratios, the energy per pound of gas is not sensitive to the magnitude of k, within the normal range. For this reason, it is often sufficiently accurate to use k_0 with no allowance for the pressure effect. This is particularly true for components of a gas mixture the partial pressures of which are low. Curves of k_0 plotted against T for several gases are shown in Fig. 19.

(Refer to Bibliography 1.)

Selecting Mean Isentropic-Expansion Exponent k

It is often possible to select, by inspection from the curves, a value of mean k which is sufficiently accurate for ordinary requirements. Where greater accuracy is required, the following method will help:

Consider first the case of a gas for which only curves of k_0 against temperature are available. The end temperature T_2

[5] Numbers in parentheses refer to the Bibliography at the end of the paper. References 1 to 12, inclusive, deal with p-v-T data; references 13 to 17, inclusive, deal with specific heats at zero pressure, as used in calculating isentropic-expansion exponents at zero pressure.

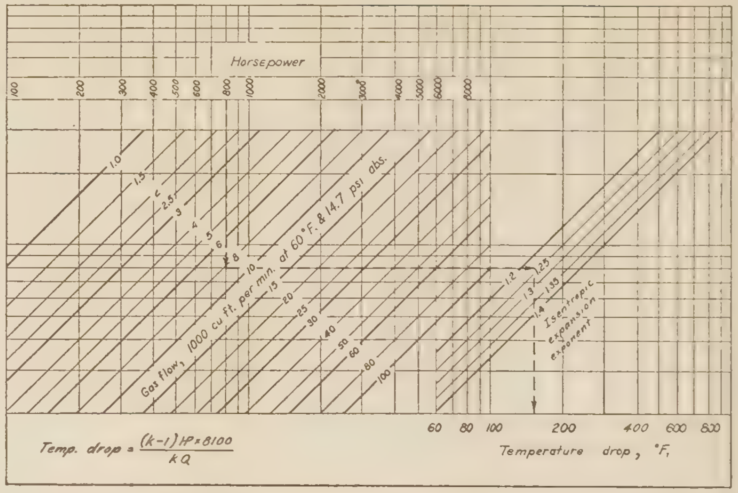

Fig. 20 Gas-Temperature Drop Through Turbine

for isentropic expansion can be calculated, using an assumed value of mean k from the formula

$$T_2 = T_1\left(\frac{p_1}{p_2}\right)^{\frac{1-k}{k}} \quad \text{[7]}$$

A mean value of k between T_1 and T_2 can then be determined. Usually it is sufficiently accurate to use the value of k at the mean temperature $(T_1 + T_2)/2$.

If curves of k are available for a sufficient range of both temperature and pressure, calculate T_2 by Equation [7]. If the temperature drop is small, it will be sufficiently accurate to use $k_m = (k_1 + k_2)/2$, where k_1 is read from the curves at p_1 and T_1, and k_2 at p_2 and T_2.

Since the path of isentropic expansion on the $(k - T)$ plane may not be a straight line, it will be well, in the case of large pressure ratios, to divide the temperature drop into two or more approximately equal parts. The end pressure for each successive expansion can be determined from the formula

$$p_2 = p_1\left(\frac{T_1}{T_2}\right)^{\frac{k}{1-k}} \quad \text{[8]}$$

the subscripts in this case referring to the beginning and end points of the partial expansions. A mean value of k can then be determined for each partial expansion and these averaged to obtain an over-all k_m.

If it is found that the assumed value of k_m used in Equation [7] is too far off from the final value, the process must be repeated.

In the case of gas mixtures the accuracy of this method will depend also upon the accuracy of the method used for obtaining the combined properties, as well as on the time which can be given to deriving curves of combined properties. Combined values of pv/T based on Amagat's law are usually more reliable at high pressure than those based on Dalton's law. Combined values of pv/T for many of the hydrocarbon gases and some others can be obtained with good accuracy from charts of generalized properties, based on reduced pressures and temperatures and on pseudo critical pressures and temperatures. This method was developed by W. B. Kay (10), and is described by Hougen and Watson (11). This book contains a great deal of useful information on gases and gas mixtures. What is probably a yet more accurate, but rather laborious method, also described by Hougen and Watson, was developed by Prof. E. R. Gilliland (12) of the Massachusetts Institute of Technology.

Assuming Amagat's law to hold, an assumption which is sufficiently accurate for most work at any but very high pressures, combined values of pv/T can be readily obtained from the formula

$$\text{Combined } \frac{pv}{T} = \frac{p_1v_1}{T_1}b_1 + \frac{p_2v_2}{T_2}b_2 + \ldots \quad \text{[9]}$$

The subscripts 1, 2, etc., here refer to the individual values for the several component gases taken at the same pressure and temperature that are being considered for the mixture. Terms b_1, b_2, etc. are the fractional parts by weight of the component gases.

A method of obtaining values of combined k, which is justified by the perfect-gas laws, has been proposed by Allen Keller.[6] It is doubtful whether the effective error, due to the use of this method with actual gases is of appreciable magnitude except at extremely high pressures. No more suitable method is known to the authors. In this method

$$\text{Combined } k = \frac{\sum \frac{ak}{k-1}}{\sum \frac{a}{k-1}} \quad \text{[10]}$$

in which a is the fractional part by volume of a component.

Changes from fractional parts by weights to fractional parts by volume and vice versa can be made by means of the formulas

$$a = \frac{bM}{m}, \quad b = \frac{am}{M}, \quad M = \Sigma(am), \quad \frac{1}{M} = \Sigma\left(\frac{b}{m}\right)$$

If many energy calculations will be required for a given gas mixture, it will be well to compute values of combined pv/T and k over sufficiently wide ranges and plot curves. This will be found much simpler than working up a Mollier chart for the gas on a scale which will give corresponding accuracy.

The approximate temperature drop from turbine inlet to exhaust can be obtained from the nomograph in Fig. 20, when the horsepower, corresponding to a given volume flow and isentropic-expansion exponent, is known.

Although the calculation method just described is derived for theoretical power outputs of superheated gases, experience with steam and mercury indicates that the supersaturation effect will

prevent any serious inaccuracy in using it for calculating turbine outputs for expansions down to approximately one half of the pressure at which the isentropic expansion crosses the saturation line or the dew line, in the case of a compound gas. The turbine efficiency used should be that based on complete superheated-gas expansion. Exhaust temperatures, determined from Fig. 20, may however be incorrect in such cases. Vapor-pressure curves for several gases are given in Fig. 21.

Fig. 22, showing the comparative physical sizes of turbines operated by several gases, may be of some interest. The turbine operated by mercury is assumed to have one expansion stage. The numbers of expansion stages for the other turbines are in proportion to the available energies of their gases, as compared to the available energy for the mercury. The relative number of stages is indicated by the turbine-barrel length, as compared with that of the mercury turbine. The comparative inlet and exhaust sizes, worked out on a consistent basis, are also shown in Fig. 22.

Certain useful data on various gases are given in Table 1.

SUMMARY

1 It is probable that many engineers, who are associated with or considering processes in which gases are available under pressure, will welcome a simple and accurate method of estimating the power output which can be obtained from a flow of gas expanding in a turbine between given pressures. Such a method is given in this paper.

2 Certain processes may be improved or operated more economically by the installation of turbines to derive power from the expansion of gases whose energy might otherwise be wasted or inefficiently used.

3 In some cases, the reduction in temperature resulting from expansion through a turbine may be more important than the power obtained.

4 By expanding gases through turbines rather than wastefully through valves and small pipe lines, power can often be derived which will replace power derived from the burning of fuel, and thus help to conserve our fuel resources.

(a) *Derivation of Output From Fig. 5.* From the k_0 curves in Fig. 19, select by inspection an approximate mean value of

isentropic exponent. The relative portions of the various component gases and the locations of the curves indicate that k_m for the combined gas will fall slightly below the curve for methane. As a mean temperature, we may take 100 less than the initial temperature. Since the k_0 curves are plotted against absolute temperature, the mean temperature will be 340 — 100 + 460 = 700 R. It would appear then that a value of 1.24 for mean k is approximately correct.

This example is shown plotted in Fig. 5, the dash lines and arrows indicating the path to be followed in working out a solution with this nomograph. The operating conditions chosen for the example, together with the efficiency assumed in the nomograph, give a turbine shaft horsepower of approximately 800.

(*b*) *Derivation of Output From Properties of Component Gases, the Perfect-Gas Energy Formula, and an Assumed Turbine Efficiency.*

Component	Volume fraction or molecular fraction a	Molecular weight m	am	Weight fraction $b = am/M$
Methane........	0.8211	16.03	13.15	0.666
Ethane.........	0.0753	30.05	2.26	0.114
Propane........	0.0426	44.06	1.88	0.095
Nitrogen........	0.0140	28.02	0.39	0.020
Carbon dioxide..	0.0470	44.00	2.07	0.105
			M = 19.75	1.000

Assume k_m = 1.24 as in example (*a*). From Equation [7]

$$T_2 = 800 \left(\frac{75}{15}\right)^{-0.1935} = \frac{800}{1.365} = 586 \text{ F abs}$$

$$Tm = \frac{800 + 586}{2} = 693 \text{ F abs}$$

Values of k_m for the component gases are read from the curves in Fig. 19, at 693 R, and values of pv/T from Figs. 12, 13, 14, 8, and 10, at 75 psi abs and 800 F abs.

Component	k_m	$\frac{a}{k_m - 1}$	$\frac{a\,k_m}{k_m - 1}$	$\frac{p_1v_1}{T_1}$	$b \times \frac{p_1v_1}{T_1}$
Methane..........	1.26	3.156	3.977	0.669	0.445
Ethane...........	1.15	0.502	0.578	0.355	0.041
Propane..........	1.11	0.387	0.430	0.238	0.023
Nitrogen..........	1.395	0.035	0.049	0.384	0.008
Carbon dioxide....	1.255	0.184	0.231	0.243	0.025
		4.264	5.265		0.542

$$\text{Combined } k_m = \frac{5.265}{4.264} = 1.235$$

In Fig. 15, at $k = 1.235$ and $\frac{p_1}{p_2} = 5$, $\frac{E}{p_1v_1} = 0.258$

$$\text{Combined } \frac{p_1v_1}{T_1} = 0.542$$

$E = 0.258 \times 0.542 \times 800 = 111.8$ Btu per lb

The gas flow is 8000 cfm at 60 F (520 F abs) and 14.7 psi abs

$$v = \frac{380}{M} = \frac{380}{19.75} = 19.23$$

$$\text{Weight flow} = \frac{8000 \times 60}{19.23} = 24{,}960 \text{ lb per hr}$$

$$\text{Theoretical horsepower} = \frac{24{,}960 \times 111.8}{2545} = 1096$$

Assuming a turbine efficiency of 0.725, the turbine shaft horsepower is 795.

Discussion

D. J. Bergman.[7] From the viewpoint of the turbine manufacturer this presentation gives valuable information for establishing the power available from gas or vapor under pressure in industrial plants.

This subject is especially interesting, at the present time, to the oil refiner. For a number of years the refining industry has been improving the efficiency of its processes. In recent years, gas formerly burned in field torches has been processed in newly developed plants for the production not only of motor fuel but aviation fuel and chemicals as well. This has reduced the refiner's available fuel supply.

[7] Engineering and Development Department, Universal Oil Products Company, Chicago, Ill. Mem. A.S.M.E.

A further reduction has come about through elimination in large part of acid-treating and improvement of residual fuels to the point where there is practically no unsalable fuel product produced in a refinery. This has changed the refiner's fuel picture from one of disposal of a product for its nuisance value to that of the need for rigid economy in minimizing the use in the refinery of otherwise salable products. In line with the increasing trend toward fuel economy has been the installation of superheaters, steam generators, and the use of exhaust steam from other services in low-pressure turbines.

Under present conditions with the government's call for tripling the aviation-fuel capacity in this country, yet greater reduction in refinery-gas supply must result, and direct generation of power will be one answer to the problem.

Application of a turbine directly in a refining process, using gas or vapor, involves a number of considerations which do not occur in connection with generating power by steam. Aside from the very different thermodynamic properties of the material there are problems due to corrosion, dust, high temperatures, refrigeration of gas, formation of hydrates, and the hazards involved in using combustible materials.

Natural gas has been used as a motive power for driving pumps in many instances, particularly in connection with the natural-gasoline industry. However, leakage past stuffing boxes has been rather a serious matter and at least one bad refinery fire has occurred as a result. Where leakage of steam would be of no consequence whatever, careful thought must be given to the possible effects of leakage of combustible gas, and provisions for ventilation or sealing fluids must be made to cut down the hazards. In many cases, special alloys will be required because of the corrosive properties.

P. V. Keyser, Jr.[8] The authors have presented a method of estimating the energy available in gases under pressure for deriving power by the use of suitable expansion turbines. The work is of considerable engineering value for future developments in this field. In addition, the authors suggest specific applications for equipment of this type in process industries.

In this connection some comments regarding the use of gas turbines in catalytic cracking may be of interest. In our domestic refineries we now have nine gas-operated turbines, generating a total of more than 25,000 hp, and several more are under construction.

These turbines are used on Houdry catalytic cracking units. Their purpose is to drive the 2500-hp compressors which provide compressed air for burning deposits from the catalyst. The gas turbines are driven by the compressed air after it has served its purpose in the catalyst cases.

There is some pressure drop through the catalyst cases, but the temperature of the air increases during the burning operation so that enough power is usually derived from the regeneration gases to compress the air. It can be seen that a considerable saving in power is realized in this operation by the use of gas turbines.

The regeneration gases used to drive the turbines vary considerably in composition, being rich in CO_2 and poor in O_2 at the start of regeneration, and poor in CO_2 and rich in O_2 at the end of regeneration. The average composition is approximately as follows:

	Per cent
Water vapor	8
Carbon Dioxide	10
Oxygen	7
Nitrogen	75
	100

[8] Technical Service Division, Socony-Vacuum Oil Company, Brooklyn, N. Y.

Some of these turbines have been in operation for more than 2 years and have given remarkably little trouble, considering the high rotational speeds at which they operate.

As for other possible uses for gas turbines, the petroleum-refining industry offers many applications where power could be derived from high-pressure gases. The disadvantage in most cases is that the power produced must be used by the unit producing it, because the source of power will be eliminated when the unit is shut down for cleaning out or inspection.

If, for instance, the power is used to generate electricity for use at the refinery, there must be some other source of power during shutdowns of the unit producing the power. Demand charges of public-utility companies, or auxiliary-equipment costs, will often seriously reduce the savings made by use of the turbines.

One other problem in using gas turbines at oil refineries, even when the power is used at the unit producing the power, is that outside power must be used in many cases, when starting up the unit.

For the turbocompressors at the Houdry units, a burner is placed in the compressed-air line, so that the air can be heated even though no deposits are being burned. Also, a steam turbine or electric motor is connected to the system for use in starting. No doubt, similar solutions could be found for problems in connection with other applications of gas turbines in oil refineries.

The potential savings possible by using gas turbines in oil refineries are large. The principal reason why such installations have not been made in the past was doubt as to their reliability. The losses which would be suffered if a large cracking unit had to be shut down, because of a gas-turbine failure, would outweigh any savings which could be made by using the turbine. Now that gas turbines have been proved reliable, we believe that such installations will be made in increasing numbers in the future.

The paper under discussion should be of considerable value to engineers analyzing the operation of existing gas turbines and considering the economics of proposed installations.

Authors' Closure

The fact, mentioned by Dr. Bergman, that the oil refiner is now concerned with the generation of by-product power rather than the useful disposition of waste heat is a condition which is now more or less common to all thermodynamic processes, in which efficiency and economy are of first importance.

Dr. Bergman has also pointed out some of the special problems, such as corrosion, dirt, and inflammability, which will be encountered with certain gases. These problems must, of course, be anticipated in the design of the turbine. The hydrogen-cooled generator furnishes an example of what may be done to avoid explosion hazards.

The temperature of gases used in turbines will frequently be high. In recent years a wealth of operating experience has been accumulated with steam, mercury vapor, and combustion gases at temperatures between 900 and 1000 F. Some experience also has been obtained with combustion gases at still higher temperatures.

While the thermodynamic properties of a gas will have an important effect on the design of the turbine, designs can be made for efficient utilization of the expansion energy of almost any gas through wide ranges of flow, temperature, pressure, and pressure drop without exceeding the limits of stress and rotational speed encountered with steam turbines.

Mr. Keyser has brought out the very important point that in some turbine applications none of the normal operating gas will be available for starting. In some cases it may be practical to pass steam through the gas turbine to start it, then gradually change to operation with gas.

The authors have observed that nearly all engineering problems could be solved if economic considerations were neglected. Obviously economic considerations cannot be neglected, so the state of progress of gas turbines has been determined by the economics of gas processes into which the turbines fit. It is entirely possible that in the period immediately following the present emergency, the need for fuel economy will require the development of many new sources of power, and at that time further development of gas turbines and gas processes will be economically practical.

The Application of the Girbotol Process to Industry

By B. D. Storrs,[1] and R. M. Reed[1]

Details of the Girbotol process for the removal and recovery of acid gases, such as hydrogen sulphide and carbon dioxide, with amine solutions are outlined in this paper, and its many applications to industry are described. These fields include: Purification of natural and refinery gases; removal of carbon dioxide from raw hydrogen and hydrogen-nitrogen mixtures; carbon-dioxide and hydrogen-sulphide recovery; and the production of inert atmospheres.

In 1928, the necessity of finding an economical means of removing large percentages of carbon dioxide from helium-bearing natural gas led to the discovery of the Girbotol process. This is a simple cyclic process for scrubbing and recovering acid gases from gaseous mixtures. Gases are scrubbed with solutions of organic bases (amines) to remove acid gases such as hydrogen sulphide and carbon dioxide. The absorbed acid gases are then separated from the amine solutions by heating which reactivates the solutions for further use. This reactivation is made possible by the fact that amine salts of weak acids dissociate at moderately elevated temperatures so that the amines may be separated from acid gases which they have absorbed at lower temperatures. The process has become well established and has proved to be an efficient and economical method for separating hydrogen sulphide or carbon dioxide from natural, refinery, and other gases, as well as from the combustion products of various fuels. The purpose of this paper is to acquaint those not intimately associated with natural-gas or petroleum technology, or chemical manufacture, with the many and varied applications of this process, which is finding an increasing field of usefulness in industry.

The Girbotol Cycle

Fig. 1 shows a typical flow diagram of the process. The equipment consists of an absorber tower in which the gas is scrubbed by amine solution to remove hydrogen sulphide or carbon dioxide therefrom, a reactivator tower in which hydrogen sulphide or carbon dioxide is boiled out of the amine solution to reactivate it for further use, and the necessary heat exchangers and pumps for handling the solution. Raw gas, containing hydrogen sulphide or carbon dioxide, flows into the base of the absorber which is a bubble plate or packed tower. Lean amine solution enters the absorber near its top and flows in countercurrent relation to the rising gas, absorbing hydrogen sulphide or carbon dioxide in its downward passage. Purified gas leaves from the top of the absorber.

Rich amine solution, containing the removed acid gas, flows by absorber pressure or is pumped from the base of the absorber through the heat exchanger and thence into the upper section of the reactivator.

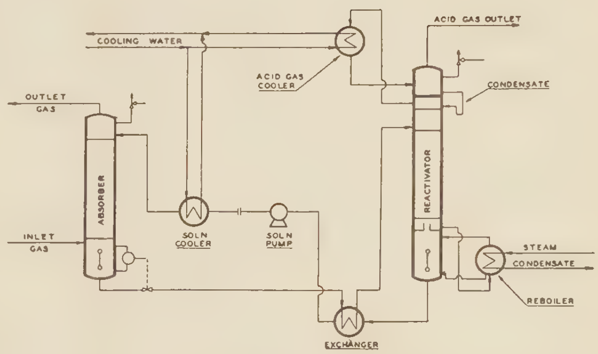

Fig. 1 Flow Diagram for Typical Girbotol Process (Patented.)

The reactivator is also a bubble plate or packed tower. In or near its base there is a reboiler which is an indirect-heating element supplied with low-pressure steam, or other suitable hot medium, for boiling the amine solution and expelling the acid gas. As the solution flows down the reactivator it is heated by ascending steam generated in the reboiler, and the hydrogen sulphide or carbon dioxide is expelled from the solution. In the reboiler, the solution reaches its boiling point which is usually slightly above the boiling point of water.

Reactivated amine solution flows through the heat exchanger and is then pumped through the solution cooler back to the top of the absorber.

Hydrogen sulphide or carbon dioxide and steam flow together from the top of the reactivator to the acid-gas cooler, where the temperature of the mixture is reduced to atmospheric and the steam is condensed. The condensate returns to the top of the reactivator as reflux, and the cooled acid gas in pure concentrated form flows to disposal or recovery.

Purification for Helium Extraction From Natural Gas

As mentioned, the first plant utilizing this process was built to treat a helium-bearing natural gas which contained a high concentration of carbon dioxide. Complete carbon-dioxide removal is necessary in helium extraction to prevent freezing difficulties in the liquefaction stage of the cycle. The early plants extracted helium from natural gases containing only small amounts of carbon dioxide which could be separated by caustic scrubbing. The helium content of these gases was in the order of 1 to 2 per cent so that it was necessary to process large volumes of gas per unit of helium recovered. A natural-gas pool containing 8 per cent helium was then discovered, but it was also found that the mixture contained about 15 per cent carbon dioxide. Caustic-soda scrubbing for this quantity of carbon dioxide would have been prohibitively expensive and, after investigating other available processes, it was decided that a new method for carbon-dioxide removal must be found—another case of necessity being the mother of invention. So it was for this original purpose that the Girbotol process was developed. It was soon recognized that the new process had general application for

[1] The Girdler Corporation, Louisville, Ky.

Contributed by the Process Industries Division and presented at the Fall Meeting, Louisville, Ky., October 12–15, 1941, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

carbon-dioxide absorption, and that it was equally useful for separating hydrogen sulphide from gas mixtures.

Natural-Gas Purification

Following quickly upon the successful operation of the first carbon-dioxide-removal plant, the process was applied to the removal of hydrogen sulphide from sour natural gas. At present, this is its broadest field of usefulness, and one in which it accomplishes a high degree of purification. Regardless of the initial hydrogen-sulphide content, sour natural gas can be processed and made suitable for domestic and industrial purposes. Numerous Girbotol plants now purify natural gas for pipe-line distribution in this country and Canada.

Simultaneous Purification and Dehydration of Natural Gas

At this point, mention should be made of a more recent modification of this process to effect simultaneous purification and partial dehydration of natural gas. The amines themselves are extremely hygroscopic and when a concentrated amine solution, or one which is fortified with another hygroscopic agent such as diethylene glycol, is circulated in the Girbotol cycle, the mixture removes both hydrogen sulphide and moisture from the gas. In this manner the solution reduces the water dew point of the gas sufficiently to prevent the formation of hydrocarbon hydrates in the transmission lines, thus eliminating line-plugging and interference with compressor operation, two very troublesome factors in pipe-line distribution. Most of the natural-gas plants in which this process is applied have now incorporated dehydration. The combination process for separating acid gases and water vapor simultaneously has also found application in other fields, such as purification and dehydration of natural gas for liquefaction and storage.

Uses in Petroleum-Refining Operations

By 1930, petroleum refiners had developed hydrogenation processes for improving lubricating oils and other petroleum products. The large quantities of hydrogen needed were obtained by a new process in which refinery or natural gas is treated with steam at high temperatures in the presence of catalysts to produce hydrogen by a modified water-gas reaction. The raw hydrogen obtained by this process contains about 20 per cent carbon dioxide. The Girbotol process is widely employed for removing the carbon dioxide from this mixture to produce essentially pure hydrogen. These plants are highly successful and are now in use in refineries producing improved lubricating oils and aviation gasoline in the United States, England, and the Netherlands East and West Indies.

Perhaps the largest potential field for the process lies in petroleum refining for the removal of hydrogen sulphide and sometimes carbon dioxide from refinery gases and liquids. Polymerization processes, the synthesis of isooctane, neohexane, and various organic chemicals, such as the aliphatic alcohols and glycols, as well as the production of hydrogen and liquefied hydrocarbon gases, all are improved by the use of sulphur-free starting materials. In some instances, catalysts are injured by hydrogen sulphide. In others, expensive aftertreatment, or methods which impair the quality of the finished product must be resorted to if hydrogen sulphide is present in the charge stock. Frequently sulphur specifications are so rigid that pretreatment is essential. In all cases, the corrosive effect of hydrogen sulphide on the process equipment and pipe lines is eliminated by its removal.

Recovery of Hydrogen Sulphide for Sulphuric Acid

Another application for refinery-gas purification is the recovery of hydrogen sulphide for sulphuric-acid manufacture. Several refiners have plants in operation and others are contemplating installations. Hydrogen sulphide usually can be recovered more cheaply than sulphur can be purchased, and hydrogen sulphide can readily be burned to sulphur dioxide which is converted to sulphuric acid.

Liquid-Hydrocarbon Purification

Although the process is firmly established in the gas-purification field, it is not generally known that the same reagents and principles may be applied to the treatment of certain liquid hydrocarbons with equal or even better success. This fact is becoming increasingly important because many of the newer processes in the refining field, such as preparation of polymerization feed stocks, require the removal of hydrogen sulphide in the liquid phase.

Carbon-Dioxide Recovery

The process is useful in the separation and recovery of carbon dioxide from stack gas for the production of liquid carbon dioxide and dry ice. Many of the carbon-dioxide recovery plants operate as completely integrated units in which a fuel is burned in a boiler to produce stack gas and steam, the carbon dioxide is extracted from the stack gas, and the steam is used first for power for compression and then for heat for expelling the carbon dioxide from the absorbing solution. The fuel fired to the boiler furnishes the raw material, heat, and power. Ten years ago dry-ice manufacturers were using sodium- or potassium-carbonate solution as the absorbing medium for carbon dioxide, and had perfected a balanced system, firing just enough fuel to furnish the power and steam for the carbon dioxide which was recovered. Although balanced, this system was not efficient, since only about 50 to 70 per cent of the carbon dioxide produced could be absorbed from the stack gases by these absorbents. Excess carbon dioxide passed out the top of the absorbers unabsorbed. Since that time, improvements in steam-generating and power-producing equipment have greatly decreased the amount of fuel which must be burned to produce the power for compressing and liquefying carbon dioxide. With the old absorption processes, these improvements could not be put to profitable use, since the same amount of fuel had to be burned as before to recover a given quantity of carbon dioxide. Consequently, the newer power-production improvements threw the old carbon-dioxide-recovery cycle out of balance. In a modern Girbotol carbon-dioxide-recovery plant, as much as 95 per cent of the carbon-dioxide content of the stack gas is recovered. The liquefaction of this increased quantity of carbon dioxide utilizes all the power available from burning the fuel, while the exhaust steam from the compression cycle is sufficient to separate the absorbed carbon dioxide from the amine solution. The system is again balanced, but with a much higher over-all efficiency than was possible under the old system.

Operating on combustion gases from coal, coke, oil, and natural gas, the process is being employed to recover pure carbon dioxide for the many uses to which liquid carbon dioxide and dry ice are put. In addition, carbon dioxide being recovered by this process is used in the safety mining of coal, for the production of soda ash, and even in the manufacture of aspirin. Plants are located in the United States, England, Cuba, the Philippines, New Zealand, and the Malay States.

The process is particularly economical for carbon-dioxide recovery when natural gas is available as a fuel. Flue gas from natural-gas-fired boilers contains only about 10 per cent carbon dioxide, as against 14 to 20 per cent for solid and liquid fuels. The high absorptive capacity of the amines for carbon dioxide makes natural gas a practical fuel for carbon-dioxide production,

and natural gas has been substituted for coke in some existing plants after the alkali-carbonate solution has been replaced with the present process.

Production of Inert Atmospheres

Quite recently the importance of controlled atmospheres in the heat-treatment of steels and special metals has been recognized. In order to meet the steadily increasing standards of quality in metallurgical products, it has been necessary to produce an essentially inert atmosphere for use in treating certain grades of metals. The present crisis necessitates uninterrupted production, which is facilitated by the proper processing of working tools. The heat-treating processes employed are annealing, normalizing, quenching, and preheating for the hot-shaping of steels by rolling, forging, and pressing. All of these heat operations can be greatly improved if carried out in inert atmospheres. The most suitable atmosphere for heat-treating metals is one consisting essentially of pure nitrogen.

A nitrogen atmosphere is produced by burning fuel gas in the proper quantity of air to convert the oxygen to carbon dioxide and water. These are then removed from the products of combustion. Here again the process fits nicely into the picture. A combustion apparatus or "atmospheric-gas converter" is controlled to produce a gas essentially free from oxygen, but containing carbon dioxide and water vapor, which are removed by treatment with a dehydrating solution of amine and glycol. Final water removal is effected by aftercontact with silica or alumina gel. Since the inert atmosphere can be recirculated and make-up is required only for leakage, small generator plants are built. There are now many of these small plants operating in this country.

In the field of munitions manufacture, the process also plays an important rôle in supplying an inert atmosphere which is used to minimize explosion and fire hazards in powder-drying and bag-filling operations.

Removal of Carbon Dioxide Before Ammonia Synthesis

Yet another use of the process in the manufacture of munitions is the removal of carbon dioxide from a raw hydrogen-nitrogen mixture prior to ammonia synthesis. This is essentially the same problem that exists in the production of purified hydrogen for hydrogenation in petroleum refineries. The other commerical method of purification in this field is water scrubbing at high pressures. The Girbotol process is more effective in obtaining a carbon-dioxide-free product. However, the choice of process lies in the available fuel from which the hydrogen is produced, and the manner in which the investment may be written off. The Girbotol process shows higher economy when operated on synthesis gas from natural or refinery gas than from such starting materials as coal or coke. The temperature and availability of water is a factor which has a decided bearing on the water-scrubbing operation, but affects the subject process only slightly. This process permits the economical use of steam-driven compression equipment, employing the exhaust steam to reactivate the solution.

The manufacturers of hydrogenated edible oils also take advantage of the process in preparing their hydrogen. With improved methods of hydrogenation being developed for this industry, this process will play an important part in replacement of the older processes.

From this review of its applications it may be seen that the Girbotol process offers operating economies in many diversified fields. The simple invention of 1928, originally developed for the express purpose of removing carbon dioxide from helium-bearing natural gas, now occupies an important place industrially. There are now 102 plants in successful operation throughout the world, covering the many fields mentioned. There is every reason to believe that many new applications will be found and that the process will continue to make a worth-while contribution to industry, as it has done in the last 12 years.

Discussion

R. J. Bender.[2] One handicap of automotive Diesel engines on the highways is the strong acrid odor of the exhaust gases. Experiments seem to indicate that it is due to the presence in the exhaust of acrylic aldehydes in various proportions, according to the make of engine, process of combustion, etc.

Would the Girbotol process lend itself to the absorption of these objectionable aldehydes in the exhaust gases? If it is feasible, there might be a field for small portable installations to clean the exhaust gases on trucks and busses, powered by Diesel engines. Naturally the carbon dioxide present in the exhaust gases to the extent of 4 to 10 per cent would be absorbed at the same time, but inasmuch as the process is of the regenerative type and as some waste heat is available for that regeneration, CO_2 absorption would not be an objection.

Authors' Closure

The Girbotol process has very recently found application in another industry, namely, the manufacture of magnesium. The chemical-engineering division of the Todd-California Shipbuilding Corporation is operating a new magnesium plant at Permanente, Calif., near San Jose. Published reports advise that this plant produces magnesium by the Hansgirg process, in which magnesium oxide (obtained by calcining magnesite) is reduced with coke in an electric reduction furnace at about 2000 C to produce metallic magnesium and carbon monoxide. The mixed vapors of magnesium and carbon monoxide emerge from the furnace and are quenched with a large volume of natural gas. This quenching with inert gas is necessary because, at lower temperatures, magnesium and carbon monoxide are recombined to give magnesium oxide.

The magnesium dust is separated by settling and by electrostatic precipitation from the stream of natural gas. A portion of the gas is then cooled and recycled through the quenching process. About one fourth of the gas is continuously withdrawn and is used for fuel in an adjoining cement plant, operated by the same company. This quantity is made up by fresh natural gas added continually to the system. The fresh gas is added in order to keep the carbon-monoxide content of the circulating quench gas at a low point.

[2] Fuel Oil Engineer, Sinclair Refining Co., Chicago, Ill. Mem. A.S.M.E.

When this plant was placed in operation, it was found that the natural-gas supply contained 1.5 per cent of carbon dioxide, which reacted with the magnesium and caused a considerable decrease in the yield of the reduction furnace.

A caustic-soda scrubber has been installed to handle the problem temporarily but the quantity of carbon dioxide to be removed is so large that the caustic-soda cost for complete removal amounts to several hundred dollars per day.

A Girbotol carbon-dioxide-removal plant is being installed at the present time to remove the carbon dioxide from this natural gas. In this case, the operating cost will be less than 10 per cent of that required to remove the carbon dioxide with caustic soda.

This new magnesium plant is another project carried out by Henry J. Kaiser who was one of the founders of Six Companies, Inc. which constructed the Boulder Dam. Construction of the plant was begun in March, 1941, and on September 10, the first unit with a capacity for producing 8,000,000 lb of magnesium per year was placed in operation. Two more similar units are under construction at the present time, and it is believed that more units will be installed after these have been placed in operation.

The crude magnesium obtained from the condenser on the outlet of the reduction furnace is purified by batch distillation, and a product is obtained with a final purity of about 99.97 per cent.

In answer to Mr. Shannon of the Henry Vogt Company, who asked if there are any impurities in the gases treated by the process which are detrimental to the solution, the following statement is made.

There are some constituents in the commercial-gas mixtures, which are treated by the process, which are undesirable. Sulphur dioxide is absorbed into the solution, forming amine sulphite, which regenerates incompletely. If there is also oxygen in the gas mixture being scrubbed, the sulphite is oxidized to sulphate in solution and the amine is thus neutralized by a strong, fixed acid. In such instances, it is possible to add caustic soda or soda ash to the solution in proportion to the amount of fixed amine. The addition of soda forms the sodium salt of the strong acid and frees the amine for further acid-gas absorption. After considerable quantities of the sodium salts have accumulated, it is necessary to discard the amine solution to prevent the crystallization of the sodium salts.

In reply to Mr. Bender; acrolein is an aldehyde, and it may be said generally that aldehydes react with the reagents of the subject process, forming undesirable decomposition products. The compounds which are formed cannot be readily regenerated in the reactivation cycle. Aldehydes are sometimes encountered in the treatment of industrial gases, and they may usually be effectively removed from such gases by an efficient water scrubber. Perhaps water scrubbing would be suitable for Mr. Bender's purification problem.

Corrosion of Unstressed Steel Specimens and Various Alloys by High-Temperature Steam

By H. L. SOLBERG,[1] G. A. HAWKINS,[2] AND A. A. POTTER[3]

Inasmuch as steam temperatures in modern central stations are approaching those used for the commercial production of hydrogen by reaction between steam and iron, an investigation was undertaken at Purdue University of the corrosion by steam of the various steels which are available for high-temperature service. Apparatus was constructed and techniques developed for measuring the amount of corrosion on unstressed specimens due to temperatures up to approximately 1400 F, and pressures up to at least 1600 psi gage. Data are presented showing the effect of various types of surface finish and methods of scale removal, time of exposure to steam at 1100 F for various intervals of time up to 2000 hr, exposure for 500 hr at steady steam temperatures from 1000 F to approximately 1400 F, and temperature fluctuations on the corrosion resistance and spalling of scale on round bars, as well as convex, concave, and flat surfaces. Data on the corrosion of cast steels and some special alloys are also given. The resistance of alloy steels to high-temperature steam is greatly influenced by the amount of chromium present. Alloy steels containing 7 per cent or more of chromium are very resistant to corrosion produced by steam at temperatures up to at least 1400 F. The 18-8 stainless steels showed practically no corrosion when subjected to steam up to 1400 F.

INASMUCH as steam temperatures in modern central stations are approaching those used for the commercial production of hydrogen by the reaction between steam and iron, an investigation was undertaken at Purdue University of the corrosion by steam of the various steels which are available for high-temperature-steam service. Apparatus was constructed and techniques developed for measuring the amount of oxidation due to temperatures up to 1200 F and pressures up to at least 1600 psi gage. Data were presented by the authors in a progress report,[4] which showed the effect of temperatures from 800 to 1200 F on the oxidation of low-carbon steel in contact with steam at 1200 psi gage. It was found that the rate of oxidation of low-carbon steel at 1100 F is independent of pressure between the minimum and maximum pressures used, which were 400 to 1200 psi.

The investigation has been continued upon unstressed specimens of a wide variety of steels and alloys and has had for its objective the determination of the effect of various types of surface finish and methods of scale removal; the effect of time of exposure to steam at 1100 F for various intervals of time up to 2000 hr; the effect of exposure for 500 hr at steady steam temperatures from 1000 F to 1300 F; the effect of temperature fluctuations on the corrosion resistance and spalling of scale on round bars as well as convex, concave, and flat surfaces; and the corrosion of cast steels and special alloys.

Methods Used for Measuring Corrosion Products

Steam reacts with steel according to the following equation

$$4H_2O + 3Fe = Fe_3O_4 + 4H_2$$

While this reaction indicates that the amount of corrosion could be measured from the quantity of hydrogen evolved, the occluded gases in the steel and the permeability of steel to hydrogen introduced variables which made the method unsuited for this investigation.

An attempt was made to measure the extent of corrosion by stripping the scale from corroded specimens by the use of hydrochloric acid, antimony trioxide, and stannous chloride. This solution failed to remove the scale from steels high in chromium, although it was satisfactory for low-carbon steel.

A series of experiments on other acid-and-inhibitor combinations was then undertaken. The main purpose of this phase of the work was to determine if possible an acid-and-inhibitor combination which would work equally well for removing the scales formed on low-carbon steel and alloys containing large amounts of chromium. Various mixtures and concentrations of nitric, sulphuric, and hydrochloric acids and inhibitors were used in an attempt to remove the scale formed on 18-8 stainless steel. A number of different inhibitors were used and it was found that a 34 per cent sulphuric-acid solution with 0.1 per cent quinoline ethiodide would remove the scale from low-alloy steels with no appreciable attack on the base metal. Table 1 gives the results for all of the inhibitors used, except quinoline ethiodide, with both 34 per cent sulphuric acid and concentrated hydrochloric acid.

TABLE 3 RESISTANCE OF CLEAN SPECIMENS OF LOW-CARBON STEEL TO ATTACK BY ELECTROLYTIC STRIPPING IN 10 PER CENT SULPHURIC ACID WITH 1 G PER L OF QUINOLINE ETHIODIDE

(Current density, 1 amp per sq in; time, 30 min)

Specimen	Weight of Specimen, grams		
	Before stripping	After stripping	Loss in Weight, grams
1	143.264	143.234	0.030
2	147.442	147.402	0.040
3	148.642	148.628	0.014
4	146.292	146.274	0.018
5	146.102	146.078	0.024
6	144.298	144.270	0.028
7	145.060	145.016	0.044

In all of the tests the low-carbon-steel samples were allowed to remain in the acid-inhibitor solution for six hours at room temperature. Quinoline ethiodide was found to be very effective in 34 per cent sulphuric acid and poor in concentrated hydrochloric acid, as shown in Table 2. The inhibiting action of quinoline ethiodide in 34 per cent sulphuric acid breaks down as the temperature of the acid increases. At 110 F very little inhibiting action remains.

While quinoline ethiodide in 34 per cent sulphuric acid worked very well for removing the scale on low-carbon steel, no combination of acids or concentrations of quinoline ethiodide could be found which would remove the scale from the steels containing 12 per cent chromium or more without pitting of the parent metal.

Consideration was given to measuring the extent of corrosion by weighing the corroded specimen, then reducing the scale by means of hydrogen at high temperature, and again weighing the specimen in order to determine the amount of oxygen present in the corrosion products. This method was discarded because of the stability of chromium oxide.

Scale removal by electrolysis was next considered. It was found that scale could be removed completely from low-alloy steels in 10 per cent sulphuric acid containing 1 g per l of quinoline ethiodide by using a current density of 1 amp per sq in. at room temperature. A density of 2 amp per sq in. removed the scale satisfactorily from 18-8 stainless steel. Tests were conducted to measure the attack on the bare metal. In 10 per cent sulphuric acid with no inhibitor and a current density of 2 amp per sq in., there was little loss in weight; however, the metal was dark in color, thus indicating some surface oxidation. With 1 g per l of quinoline ethiodide and 10 per cent sulphuric acid, no loss in weight of bare metal was detected. Additional tests were conducted to determine the effect of temperature. Up to 110 F, the metal was attacked no more than at room temperature. At higher temperatures, the attack on the metal became noticeable. Table 3 shows the results obtained in a series of tests on clean specimens of low-carbon steel when subjected to electrolytic action for 30 min at room temperature.

The method of determining the extent of corrosion by steam, which was finally adopted and used to obtain the results reported in this paper consisted of weighing the clean specimen before exposure to steam, removing the scale by electrolytic stripping after exposure to high-temperature steam, and reweighing the specimen. The solution consisted of 10 per cent sulphuric acid with 1 g per l of quinoline ethiodide. The specimen served as the cathode. The time required for effective stripping with a current density of 1 amp per sq in. was investigated and was found to vary with the chromium content of the specimen as follows:

Steel	Time required, hr
S.A.E. 1010	1/2
4-6 Cr-Moly	1
12 Cr	2
18-8	4

The earlier test specimens were made from tube stock 6 in. long, and 1 1/2 in. OD × 1 in. ID. Scale was stripped from these specimens by use of a platinum rod as the anode. Difficulty in inspecting the inside surface of the specimens for complete scale removal resulted in the subsequent use of bar stock for all specimens. The specimens machined from bar stock were stripped by means of the apparatus shown in Fig. 1. The round bar stock samples were placed in a saddle as shown which in turn was placed on insulators located on the bottom of a lead container. The solution of sulphuric acid and quinoline ethiodide was placed in the lead jar which served as the anode. The current density was regulated by means of a large carbon-pile rheostat. Heat

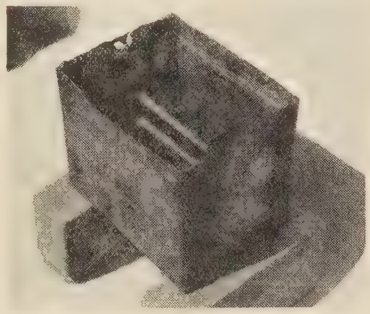

Fig. 1 Photograph of Stripping Tank and Bar-Stock Specimens

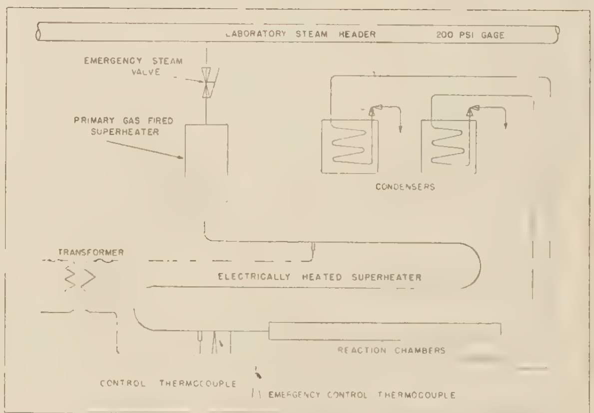

Fig. 2 Schematic Diagram of Apparatus

losses from this lead case during the stripping action made cooling devices unnecessary.

Test Apparatus

Fig. 2 is a schematic diagram of the test apparatus. The steam, after leaving the laboratory main at about 200 psi gage, passed through a counterflow gas-fired superheater. A thermocouple was located in the discharge line from this superheater. After leaving the gas-fired superheater, the steam passed through 65 feet of 18-8 stabilized stainless-steel tubing, $^5/_8$ in. OD $\times$ $^3/_8$ in. ID. The ends of this pipe were connected to a current transformer, thus converting the tubing into a resistance heater in which the final heating of the steam was accomplished.

Leaving the electric superheater, the steam was divided and flowed into two 16-ft test sections, each made from 2-in. extra-heavy pipe. The discharge end of each test section was fitted with a standard pipe cap to facilitate insertion and removal of the test samples. The steam leaving each test section passed into a coiled-copper-tube condenser. The condensate was weighed at intervals in order to maintain the proper flow rates. Needle valves were used on the discharge side of the condenser for regulating steam flow and maintaining turbulent-flow conditions around the specimens. Bourdon-tube pressure gages were used to determine the pressure in each of the test sections.

Around each 16-ft test section or reaction chamber were wrapped three electric heaters, consisting of No. 13 chromel wire insulated with refractory beads. The heaters were divided into three sections consisting of two 4-ft end-guard heaters and one main heater having a length of 8 ft. The pipes and heaters were covered with 10-in. split sewer tiles over which was placed a very thick bed of loose diatomaceous-earth insulation. Chromel-alumel thermocouples were placed every 18 in. along each test section.

Electric Circuit

The temperature of the steam leaving the electric superheater was maintained constant by means of a thermocouple, controller,

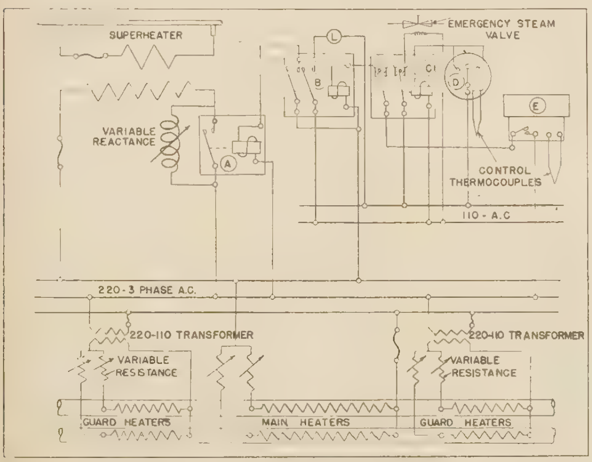

Fig. 3 Schematic Diagram of Electrical Apparatus

and magnetic switch. Fig. 3 shows a wiring diagram of the main electrical circuit. In the lower portion of the diagram are shown the main and guard heaters which surrounded the reaction chambers or test sections. The guard heaters operated on 110 v, while the main heaters were supplied from the 220-v line. Each heater was equipped with a variable resistance in order to maintain the temperature of the tubes at any desired value which was equal to the temperature of the steam supplied to them. The main power circuit for the electric superheater is shown in the upper left-hand corner of the diagram. The 2300-v winding was removed from an old transformer and replaced by a few turns of No. 0000 cable, which served as the secondary. The original 220-v winding was connected to the magnetic contactor (A) and variable reactance as shown. With the magnetic switch open only a fraction of the maximum current passed through the superheater circuit. By means of opening and closing the magnetic switch intermittently, it was possible to maintain the superheater temperature constant. The control for the magnetic switch is shown in the upper right-hand corner of Fig. 3. The thermocouple located in the discharge line from the electric superheater operated a controller (E) which actuated the magnetic switch (A) through relay (B), thereby opening and closing the circuit to the superheater transformer. Relay (C) together with the emergency controller (D) were used for opera-

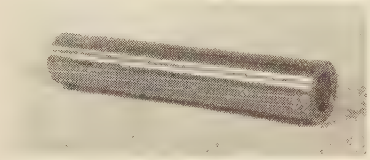

Fig. 4 Tube Specimen

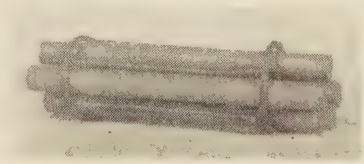

Fig. 5 Bar Specimen

tion of the emergency steam valve in the line supplying steam to the superheater. In case of a low or high superheater temperature, the emergency controller (D) operated relay (C) which opened the magnetic switch (A) and also actuated the coil connected to the quick-acting shutoff valve in the steam line. Thus the specimens were automatically protected from steam at any temperature other than the desired test temperature.

Lead wires from all of the thermocouples located in the reaction chambers were connected to a bakelite jack-board cold junction. All temperature readings were taken on a portable potentiometer.

Test Specimens

All test samples, other than those used in the surface-finish tests, were sandblasted and weighed, after which they were placed in the reaction chambers. Fig. 4 shows the type of tube specimens used. The tubes were supported on four small legs in order to align the test tube concentrically with the reaction chamber. The bar specimens were mounted in cages, as shown in Fig. 5. Upon completion of a test the bars were removed and the scale stripped, after which they were accurately weighed. Test specimens which had to be stored for any length of time were placed in a large can containing a layer of calcium chloride on the bottom and an opening on the side or top for the admission of nitrogen gas. All samples were handled as little as possible and only then with gloves in order to prevent any foreign material from contaminating the external sanded surface. All samples were carefully stamped with the classification number and the specimen number. The location of each specimen together with the cage was recorded both with regard to the position in the reaction chamber and thermocouples.

Heat-Treatment

In order to insure consistent heat-treatment of specimens, all of the steel received except the cast steels were heat-treated. Low-carbon steel was annealed at 1600 F, slow-cooled to 1200 F at a rate of 40 F per hr, and then air-cooled from 1200 F to room temperature. Steels having a chromium content between 1 and 12 per cent were annealed at 1580 F, slow-cooled to 1200 F at a rate of 40 F per hr, and air-cooled from 1200 F to room temperature. The high-chromium stainless steels were annealed at 1950 F and water-quenched. Several of the special alloy steels were annealed according to the methods suggested by the producers which deviated only slightly from the general procedure outlined.

The cast steels were received in the annealed condition which was reported to be as follows:

Cast steel	Heat-treatment
Carbon steel.......	Annealed 1650 F for 4 hr, furnace-cooled to 700 F, and air-cooled to room temperature
Carbon-Moly.......	Normalized at 1800 F for 4 hr, drawn at 1200 F for 4 hr, furnace-cooled to 700 F, and air-cooled to room temperature
Ni-Cr-Moly........	Normalized at 1725 F for 4 hr, normalized at 1550 F for 5 hr, drawn at 1200 F for 4 hr, and air-cooled to room temperature
5 Cr-Moly.........	Normalized at 1800 F for 4 hr, normalized at 1600 F for 3 hr, drawn at 1280 F for 4 hr, and air-cooled to room temperature
9 Cr-1$^1/_2$ Moly......	Normalized at 1820 F for 4 hr, normalized at 1650 F for 4 hr, drawn at 1300 F for 4 hr

Preliminary Test on Low-Carbon-Steel Tube Specimens

As the first part of the general program it was decided to test a series of specimens from one heat of steel to determine the

TABLE 4 CORROSION OF LOW-CARBON-STEEL TUBES IN CONTACT WITH 1100 F STEAM FOR 120 HR

Specimen Number	Loss in Weight of individual sample, grams	Temperature Degrees, F	Variation from the average loss in weight, percent

30-5	7.079	1098	+5.15
27-3	7.405	1095	+10.00

probable consistency of the results. Twelve identical tube specimens were cut from one tube, 1$^1/_2$ in. OD × 1 in. ID, of open-hearth S.A.E. 1015 steel and machined to size. The specimens were sandblasted and placed in the reaction chamber at a mean temperature of 1095 F with steam at the same temperature flowing past the specimens for a period of 120 hr. Considering only specimens at a temperature of ± 5 F from the mean, the results shown in Table 4 were obtained. The results obtained seemed to indicate that the method of stripping the scale and general test technique were satisfactory.

1100 F ± 5 F for time intervals of 100 hr, 200 hr, 500 hr, and 1000 hr in order to determine the effect of time on the extent of corrosion. The analyses of the various steels are shown in Table 5. Specimens of each alloy were cut from $1^1/_2$-in-OD × 1-in-ID tube stock, machined to size, and sandblasted. The results are shown in Table 5 and are represented by smoothed curves in Fig. 6. The scattered results were attributed to irregular temperature distribution and the difficulty encountered in ascertaining whether or not the scale had been removed completely from the inside surface of the tube. Nevertheless, this test does show the great influence of the chromium content upon the extent of corrosion. Due to the difficulty of removing the scale from the inner surface of the tube it was decided to change from tube to bar specimens in subsequent tests.

Effect of Surface Finish

With the adoption of bar-stock specimens having accessible surfaces, a study was made of the effect of surface finish on the bar specimens in order to ascertain whether or not sandblasting

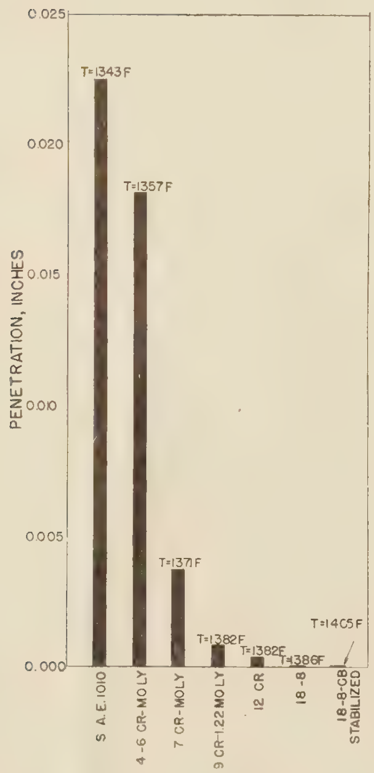

FIG. 9 CORROSION OF STEELS IN CONTACT WITH STEAM FROM 1343 F TO 1405 F FOR 300 HR

was suitable for standardizing the surfaces of the various alloys. For this study thirty-nine specimens were prepared from $^1/_2$-in-diam S.A.E. 1020 steel. Twenty-one specimens were annealed for 30 min at 1600 F and air-cooled. Of these, fourteen were surface-sandblasted, and seven surface-ground and lapped. Of the sandblasted specimens, seven were boiled in distilled water for 24 hr and then washed in ether and 95 per cent ethyl alcohol immediately before being placed in the test section. Of the eighteen specimens which were unannealed, seven were cold-worked by severe bending and straightening and finally surface-

sandblasted, seven were sandblasted, and four were sandblasted and surface cold-worked by peening with a ball-peen hammer. The specimens were placed in cages and allowed to remain in contact with 1100 F steam for 500 hr.

The results are shown in Table 6. From a study of these data, it was decided that the method already adopted of annealing and sandblasting test bars was satisfactory when cost, time of preparation, and consistency of results were considered.

Test on Bar Specimens to Determine Influence of Length of Test

The effect of time on corrosion at 1100 F for a number of different-alloy bars was next studied. Four different tests were conducted on the various alloys; the lengths of these tests were 200 hr, 500 hr, 1000 hr, and 2000 hr. Specimens of each alloy steel and low-carbon steel as listed in Table 7 were used in each of the tests. The smoothed results are shown in Fig. 7. In general, the corrosion decreases as the chromium content of the steel increases. The high-chromium steels are practically corrosion-resistant. The various 4-6 Cr steels fall in one general class, and it is not possible from this test to segregate the steels within this group. The corrosion is very rapid during the first 100 hr after which the layer of corrosion products retards the oxidation rate under steady temperature conditions. During this series of tests, from 65 to more than 80 per cent of the corrosion occurring in 2000 hr took place during the first 500 hr.

Effect of Steam Temperature on Corrosion of Bar Specimens

A series of tests was completed to determine the effect of steam temperature for a constant time on the corrosion resistance of the same steels as listed in Table 7, together with samples of carbon-moly steel. The specimens were treated in the usual manner, and subjected to steam at various temperatures. The smoothed results are shown as solid lines in Fig. 8. Except for the high-chromium steels, corrosion increases very rapidly at temperatures in excess of about 1100 F. The high-chromium steels showed very little corrosion even at 1200 F.

A special test was conducted at very high steam temperatures in order to observe the corrosion of the high-chromium steels. Seven steels as listed in Table 8 were subjected to high-temperature steam for a period of 300 hr. Heater failures prevented continuation of the test beyond this time. The results are shown in Fig. 9 and Table 8. The temperatures at which each steel was tested are shown. Steels having 7 per cent chromium or more showed very little corrosion. The 18-8 stainless steels both stabilized and unstabilized were practically unattacked at these temperatures. The results of this 300-hr test were converted to a 500-hr basis by the use of Fig. 7. This extrapolated prediction has been plotted in Fig. 8 as dotted lines.

A test on the alloy steels, shown in Table 9, was conducted for 500 hr at 1100 F. The results are shown in Fig. 10 and Table 9. As has been shown in the other tests, the chromium content has a marked influence on the corrosion. The high-copper alloy (A), and the aluminum-and-low-silicon alloy (B) show a higher corrosion than either low-carbon steel or carbon-moly steel.

Corrosion Tests on Stellite, Hastelloy, Colmonoy, and Lamite

One bar of grade 3 and one of grade 6 Haynes Stellite each 5/8 in. diam and 14 in. long were tested in contact with 1100 F steam for a total of 1300 hr. The cumulative test consisted of two 500-hr, one 200-hr, and one 100-hr tests. Examination of the surfaces after 1300 hr of testing showed that the amount of oxide

* Not a cast steel

formed was too small to determine by the stripping method. Three specimens each of Hastelloy A, B, and C were placed in contact with 1100 F steam for a period of 500 hr. A very thin layer of corrosion products was observed, which was too thin to determine by the stripping operation. Three specimens each of Hastelloy A, B, and C together with pieces of grades 3 and 6 of Haynes Stellite were placed in contact with steam at 1200 F for 1300 hr. The scale formed was very thin and the amount could not be determined by the stripping process.

Rod samples of Colmonoy and Lamite No. 4, No. 5, and No. 6 were placed in contact with steam at 1200 F for 570 hr. A very thin layer of scale formed but was too thin to measure by the electrolytic stripping method. All of these special alloys are extremely resistant to steam corrosion.

Corrosion of Cast Steels

This test was performed to determine the oxidation of several types of cast steels, the analyses of which are given in Table 10. The test specimens were machined from cast test coupons. The final specimens were 6 in. long and $^1/_2$ in. diam. The specimens were exposed to steam at 1200 F for 570 hr. Along with the cast-steel specimens, samples of 7-Cr rolled steel were placed in the reaction chamber for purposes of comparison with earlier results. The results of the test are shown in Table 10 and Fig. 11. The results from the 7-Cr steel check earlier tests within the accuracy of the experimental measurements. The corrosion decreases as the chromium content increases, as was the case with other steels having similar compositions. In general, the corrosion of cast-steel specimens is not materially different in amount from the corrosion of rolled-steel specimens.

Effect of Temperature Changes on Corrosion Rate

This phase of the general test program was undertaken to determine the effect of extreme temperature fluctuations on the corrosion of various steels. Specimens of five different unstressed steels, as listed in Table 11, were placed in contact with superheated steam at a steady temperature of 1200 F for 500 hr. At the end of this period three specimens of each steel were removed and stripped electrolytically in order to measure the loss in weight due to corrosion. One half of the remaining specimens were held at 1200 F, with sudden cooling to room temperature in nitrogen and heating again to 1200 F every 100 hr until the total time in contact with 1200 F steam was 1200 hr. The remainder of the specimens were treated similarly except for a 50-hr cooling cycle. Specimens were removed after 700 hr and at the end of the test, in order to measure the extent of corrosion.

Fig. 12 shows typical specimens at the end of the test. The first visible evidence of extensive cracking of the scale occurred after a total exposure to steam of 700 hr. The result of visual observation during the test indicated that the layer of corrosion products is thinner and more brittle as the chromium content increases up to 5 per cent. An examination of the specimens, shown in Fig. 12, indicates that the scale on the low-carbon-steel specimens was very thick, porous, and, in spite of the severe temperature shocks, spalled only slightly as compared to the 4-6 Cr steel. The 2 per cent Cr steel spalled less than the 3 per cent Cr steel while the third layer of scale was cracking in the 4–6 per cent Cr steel at the end of 1200 hr. Little scale formed on the 9 per cent Cr steel and a microscopic examination of the surfaces at the end of the test failed to show evidence that the scale had cracked or checked.

Fig. 13 is a plot of the results. It is apparent that the difference in results from the 50- and 100-hr-cycle tests is not significant. The thickness of the scale or, in other words, the time of exposure is the factor which controls cracking and spalling under temperature fluctuations for any given steel. The corrosion decreases as the amount of chromium in the steel increases.

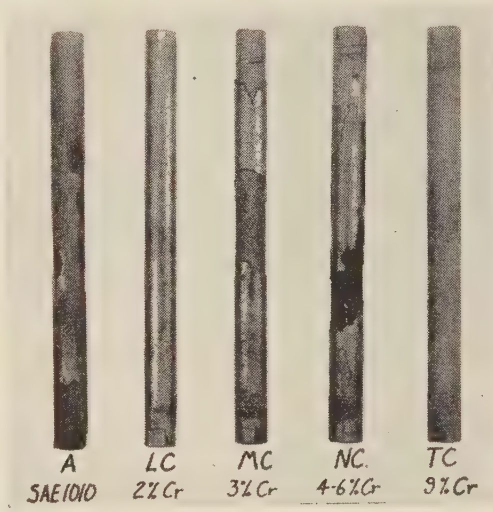

Fig. 12 Specimens Exposed to Steam at 1200 F for 1200 Hr
(Specimens cooled to room temperature every 50 hr, after a continuous exposure to steam at 1200 F for 500 hr.)

Another test was conducted in order to continue the study on the effect of intermittent heating and cooling of the test samples, and to observe the effect of the specimen-surface shape.

The ladle analyses of the steels selected for the test are shown in Table 12. Pieces of 1.5-in-OD × 1-in-ID tubing, 4 in. long, were machined externally and internally to remove mill scale, after which hexagonal flats were machined on about 40 per cent of the external surface. The specimens were then split longitudinally. The three types of surface on each piece afforded a

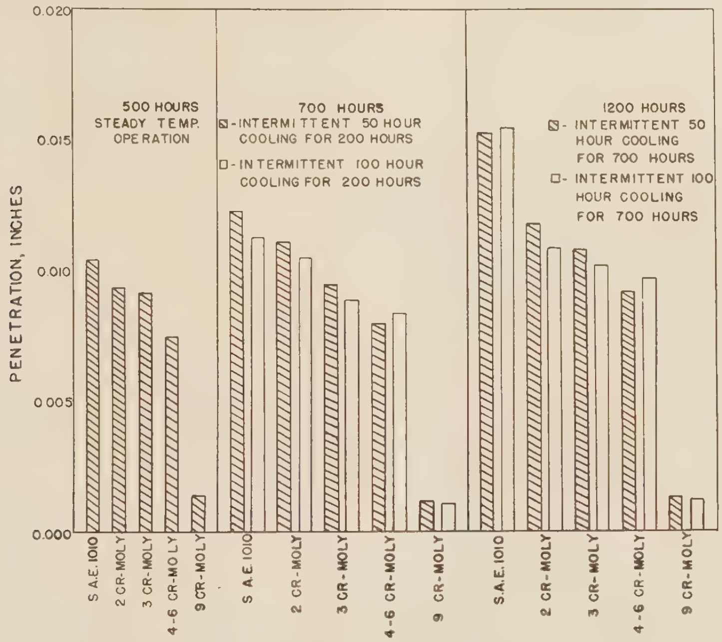

FIG. 13 CORROSION OF FIVE STEELS BY STEAM AT 1200 F WHEN SUBJECTED TO EXTREME TEMPERATURE FLUCTUATIONS

means for observing the effect of the shape of surface on the corrosion of the steel.

The specimens were placed in the steam reaction chamber at a temperature of 1200 F for 500 hr, after which they were removed and rapidly cooled in an atmosphere of nitrogen to room temperature. Two pieces of each steel were removed for use in establishing the oxidation rate for 500 hr. The remaining four pieces of each steel were placed in the reaction chamber at 1200 F. All specimens were removed, cooled to room temperature, examined, and replaced in the reaction chamber at 600, 700, 800, 900, 1000, and 1150 hr. At the end of 1300 hr of actual test time, the steel samples were removed and the penetration determined. The time intervals previously stated indicate the time the specimens were in contact with the steam and do not include the cooling or heating periods. The temperature-history chart for the test is shown in Fig. 14. This chart shows two heater failures. During these interruptions the reaction cham-

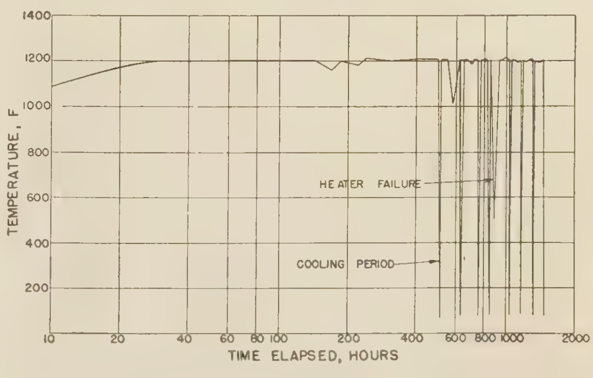

FIG. 14 TEMPERATURE-HISTORY CHART

bers were filled with nitrogen until the necessary repairs were made.

Before stripping the scale from the steel samples a 1.25-lb sphere, dropped from a height of 3 ft, struck the end of each piece four times in order to measure the adherent property of the scale.

The scale on all samples was removed at the conclusion of the impact test. After the scale was completely removed, the pieces of steel were weighed in order to determine the loss in weight from which the penetration was computed.

At the end of 500 hr, all the steel samples showed a smooth oxide coating without visible cracks in the scale. Several of the samples of 4-6 Cr-Moly-Ti stabilized showed signs of cracking of

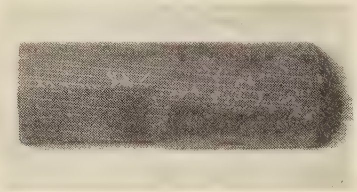

Fig. 15 4-6 Cr-Moly-Si Steel Specimen After 1000 Hr at 1200 F With Intermittent Cooling

the scale at the end of 600 hr. This was the first indication of the excessive scaling which was later observed. Samples of 18-8-Cb stabilized and 18-8 unstabilized showed very little scale formation. At the end of 700 hours flakes of scale had chipped off the samples of 4-6 Cr-Moly and 4-6 Cr-Moly-Si. The parent metal which had been exposed by the scale cracks on specimens of 4-6 Cr-Moly-Ti stabilized was again covered with a new layer of oxide. No new changes were observed when the specimens were examined at the end of 800 hours.

While the steel samples were being cooled at the 900-hr period, the noise of scale cracking from some of the specimens was audible. The scale on the specimen of S.A.E. 1010 was very thick but adhered rigidly to the metal. The scale on the pieces of 2 Cr-Moly-Al-Si and 4-6 Cr-Moly-Si flaked off in elliptical sections. This type of flaking occurred on the outer curved and flat surface, but did not exist on the inner curved surface. Scale on steels of S.A.E. 6120, 3 Cr-Moly, and Carbon-Moly, although thick, showed no signs of chipping. Complete layers of scale flaked off specimens of S.A.E. 1010 but in no case was the parent metal visible. In all the other steels the parent metal was visible after the scale flaked off. A very small scale layer formed on steels of 18-8-Cb stabilized, 18-8, 12 Cr, and 9 Cr-$1^1/_2$ Moly. The scale on 4-6 Cr-Moly-Cb stabilized was thicker than on 9 Cr-$1^1/_2$ Moly. Steels of 4-6 Cr-Moly-Ti stabilized, 4-6 Cr-Moly, 4-6 Cr-Moly-Si, and 4-6 Cr-Moly-Al-Si all showed sections where large pieces of scale had flaked off.

Fig. 15 is from a photograph, taken at the end of 1000 hr, of the 4-6 Cr-Moly-Si steel which clearly indicates the elliptical shape of the flakes of scale which had cracked from the external surface of the specimen. No appreciable changes were noticed at the end of 1150 hr. At the conclusion of the test, the scale formed on S.A.E. 1010, Carbon-Moly, 3 Cr-Moly, and S.A.E. 6120 steels was very thick but adhered tightly to the parent metal. Considerable flaking of the scale had occurred on specimens of 4-6 Cr-Moly-Ti stabilized, 4-6 Cr-Moly-Si, 4-6 Cr-Moly, 2 Cr-Moly-Al-Si, and 4-6 Cr-Moly-Al-Si. Very little scale had formed on 18-8-Cb stabilized, 18-8, 12 Cr, 9 Cr-$1^1/_2$ Moly.

The results of this test have been plotted in Figs. 16 and 17. The importance of chromium content on the resistance to corrosion is apparent from these figures. In Fig. 17, point (1) is

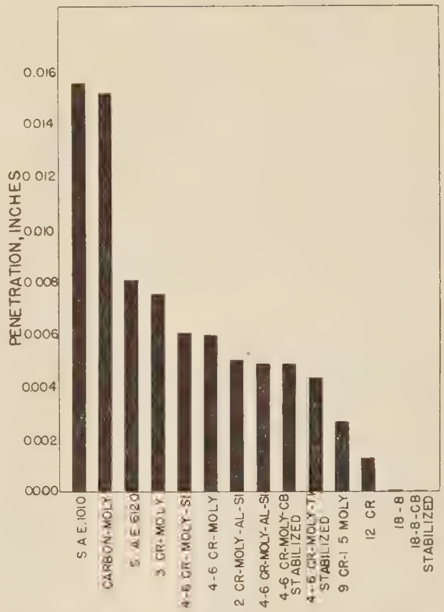

Fig. 16 Corrosion of Steels in Contact With Steam During Intermittent Operation for 1300 Hr at 1200 F

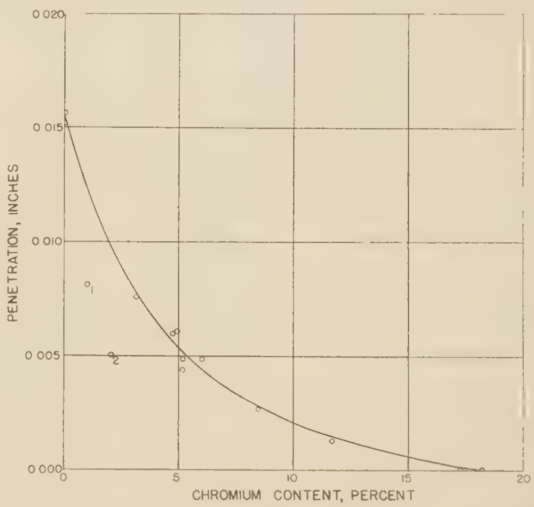

Fig. 17 Influence of Chromium Content on Corrosion of Steels During Intermittent Operation at 1200 F for 1300 Hr

for S.A.E. 6120 which is high in vanadium and point (2) is for 2 Cr-Moly steel high in aluminum and silicon. With the exception of these two points which have been neglected in constructing the curve in Fig. 17, the test points for the other steels show a good correlation between chromium content and corrosion penetration.

The steels tested for 1300 hr may be grouped into three general classes according to the scale formed: The first group consists of specimens of Carbon-Moly, 3 Cr-Moly, S.A.E. 6120, and S.A.E. 1010 which were all covered with a thick porous tightly adhering scale.

The scale formed on the steels of the second group, 4-6 Cr-Moly-Cb stabilized, 4-6 Cr-Moly-Al-Si, 4-6 Cr-Moly-Si, 2 Cr-Moly-Al-Si, 4-6 Cr-Moly, and 4-6 Cr-Moly-Ti stabilized was very brittle and flaked off the specimens during the test. The scale formed on specimens of 4-6 Cr-Moly-Si and 2 Cr-Moly-Al-

Si which were exposed to the steam at 1200 F for 1300 hr flaked off in elliptical sections. This type of flaking may be due to the silicon in the steel, since the silicon contents of 4-6 Cr-Moly-Si and 2 Cr-Moly-Al-Si were 1.5 and 1.27 per cent, respectively. Specimens of 4-6 Cr-Moly-Al-Si, which has a silicon content of 0.82 per cent, showed a slight tendency toward this type of flaking. From the visual and microscopic examination of the specimens the scale found on the inside curved surface did not flake off as much as the scale formed on either the outer curved or flat surfaces. No difference in the amount of scale flaking off the outer curved and flat surfaces could be detected.

Alloys of the third group consisting of steels of 18-8-Cb stabilized, 18-8, 12 Cr, and 9 Cr-$1^1/_2$ Moly were covered with a very thin layer of scale which adhered tightly to the parent metal.

In Table 12 the penetration for steel of 3 Cr-Moly is higher than for steel of 2 Cr-Moly-Al-Si, in spite of the fact that steel of 3 Cr-Moly has a higher chromium content than the sample of 2 Cr-Moly-Al-Si. Since 2 Cr-Moly-Al-Si contained both silicon and aluminum it may be that the combination of these two elements reduces the rate of oxidation.

The impact test showed that the oxide layers formed on samples of Carbon-Moly, S.A.E. 6120, and S.A.E. 1010 adhere to the metal as was evident by a slight amount of flaking. Practically all the outer layers of scale on steel of 3 Cr-Moly were removed during the impact test. Considerable flaking of the scale formed on steels of 4-6 Cr-Moly-Cb stabilized, 4-6 Cr-Moly-Al-Si, 4-6 Cr-Moly-Si, 4-6 Cr-Moly, 4-6 Cr-Moly-Ti stabilized, and 2 Cr-Moly-Al-Si occurred during the impact test. No scale was removed from samples of 18-8 Cb stabilized, 18-8, 12 Cr, and 9 Cr-$1^1/_2$ Moly during the impact test.

General Conclusions

1 The resistance of alloy steels to high-temperature steam is greatly influenced by the amount of chromium present. Alloy steels containing 7 per cent or more of chromium are very resistant to corrosion produced by steam at temperatures up to at least 1400 F. The 18-8 stainless steels showed practically no corrosion when subjected to steam at temperatures up to 1400 F.

2 The corrosion rate is very rapid during the first 500 hr of testing and then gradually diminishes as the time of exposure to the steam continues.

3 Steam temperatures greatly influence the corrosion of steels. Except for steels containing 7 per cent or more of chromium, the corrosion rate increases very rapidly at temperatures in excess of 1100 F.

4 The steels tested may be grouped into three general classes according to the type of scale formed. The first group consists of low-carbon steel, carbon-moly, and the low-chromium steels which are covered with a thick, porous, tightly adhering scale. The scale which forms on the steels of the second group, that is, the 4-6 Cr steels and the 2 Cr-Moly-Al-Si steel, is very brittle and easily flakes off under fluctuating temperatures. The third group consists of steels having a chromium content of 7 per cent or more upon which a very thin, nonporous, tightly adhering scale is formed.

5 Scale formed on the inner surface of a tube does not flake off as readily as the scale which has formed on the outer surface of a tube.

Acknowledgments

This investigation has been sponsored by the A.S.M.E. Special Research Committee on Critical-Pressure Steam Boilers. The authors wish to express their appreciation of the valuable assistance rendered by the members of this Committee.

In this undertaking Purdue University had effective co-operation from the Engineering Foundation, The American Society of Mechanical Engineers, The Babcock and Wilcox Company, The Detroit Edison Company, the Timken Roller Bearing Company, the Superheater Company, the National Tube Company, the Crane Company, the International Nickel Company, The Haynes Stellite Company, and the Continental Steel Corporation.

The authors are particularly indebted to C. L. Clark, research metallurgical engineer of the Timken Roller Bearing Company, Steel and Tube Division, for constructive criticism and valuable assistance rendered. Special acknowledgment is due H. J. Kerr of The Babcock and Wilcox Company, C. H. Fellows and R. M. Van Duzer, of The Detroit Edison Company, E. L Robinson of the General Electric Company, W. H. Armacost of Combustion Engineering Company, E. C. Petrie and J. J. Kanter of the Crane Company.

To the recent graduates of Purdue University, J. G. Miller, H. Templeton, W. H. Winslow, J. T. Agnew, W. R. Shade, and M. H. Davis, the authors owe a debt of gratitude, for it was through their untiring efforts that this project was brought to a satisfactory conclusion.

Discussion

C. L. Clark.[5] The authors are to be complimented on their contribution to the general subject of the effect of alloy additions on the surface stability. The point of particular interest in this respect is Fig. 17, showing the influence of chromium content on the corrosion resistance in steam at 1200 F. On the basis of this figure, chromium appears to be the predominating factor in so far as the resistance to steam attack is concerned.

Certain alloy additions do not appear to exert the same degree of protection against steam attack as against air oxidation. This is well illustrated in Fig. 18 of this discussion, in which the steam-corrosion results have been replotted on the basis of their ratio to

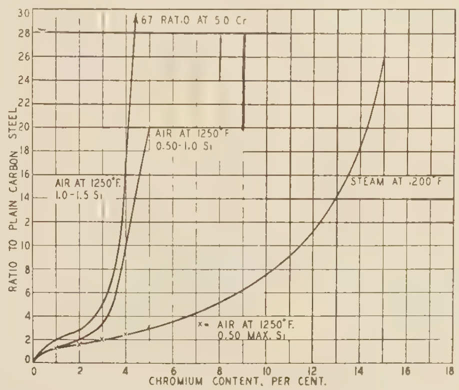

Fig. 18 Influence of Silicon Content on Oxidation Resistance in Steam and Air

carbon steel. Air oxidation tests at 1250 F, rather than at 1200 F, fall exactly on this same curve when the steels contain 0.50 per cent silicon maximum. If, however, the silicon content is either 0.50 to 1 or 1 to 1.5 per cent, then the resistance to attack in air is greatly superior to that in steam. In other words, increased silicon content is beneficial against air oxidation but not in steam.

The resistance of steels to the attack of hot petroleum products is another case in which chromium content is the main controlling factor, and a comparison of the relative influence of this element against steam and oil attack should be of interest. This condi-

[5] Research Metallurgical Engineer, The Timken Roller Bearing Company, Steel and Tube Division, Canton, Ohio.

tion is shown in Fig. 19 of this discusssion, with the results being expressed on the basis of their ratio to a 1 per cent chromium steel. The curve for the resistance to the attack of hot petroleum products expresses the results from four different refineries in which the corrosive conditions were entirely different, but in which, as shown, the relative influence of chromium content was exactly

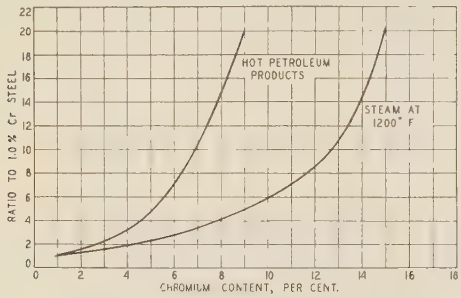

Fig. 19 Comparative Corrosion Resistance in Steam and Hot Petroleum Products

the same. These results would indicate increasing chromium content to be more effective against hot petroleum products than against steam at 1200 F.

The mechanism of attack in steam, air, and hot petroleum products must be different; and it is hoped the authors in their future work will obtain data to explain these differences between steam and air attack. The hydrogen present, because of the dissociation of the steam, may have an important influence on the type of scale formed.

R. M. Van Duzer, Jr.[6] Those who have known of the steam-corrosion research program under way at Purdue University have awaited with interest the results published in this paper. It is hoped that this work will be continued and that the other phase of the research project, dealing with the corrosion of specimens subjected to high-temperature steam and stress, also will be made available.

The writer's company has been interested in the corrosion of alloy steel from the standpoint of its attack by 1100 F steam as part of an investigation conducted in the use of high-temperature steam for power production since 1929. The corrosion phase of this work, started first as an investigation of various materials suitable for superheater tubes, was later augmented by tests on materials usable for valves and turbines when subjected both to 925 and 1100 F steam.

The tests by The Detroit Edison Company have been made using $^1/_2$-in. round $\times$ 6-in. ground-and-polished specimens which were held in a cage slipped into a steam line. Cages were or are to be removed at 4000-, 8000-, 12,000-, and 16,000-hr intervals for investigation. One group of steels, at this time, has been examined after exposure to 1100 F steam for 15,000 hr.

Among these are two, similar in composition to the corresponding steels given in Table 7 of the paper, which were exposed to 1100 F for 2000 hr. The different conclusions, which may be drawn from the authors' data and that of the writer, collected over entirely different time intervals, may be of interest.

It should be mentioned that the Purdue tests were conducted under laboratory conditions, that is, close temperature control and continuous steam flow, while the Detroit Edison samples were subjected to heating and cooling cycles and temperature fluctuations which would be encountered in commercial practice. The authors' results are the average of a number of identical tests, while the writer's results are from one specimen in each case.

In Table 13 of this discussion are listed the analyses of the two steels, together with inches penetration, service hours, and number of heating and cooling periods. The specimens were annealed and the weight-loss determinations were made in a manner similar to that followed by the authors.

Plotting these results and drawing smooth curves by the method of least squares, the results shown in Fig. 20 of this discussion are obtained. If the smoothed values from Fig. 20 are plotted on log-log paper, together with the smoothed results from Fig. 7 of the paper, two different conceptions of steam corrosion are evident from Fig. 21 of this discussion.

The authors' results indicate that loss of weight with time follows a power relation, while the writer's results indicate the relationship is much more complex, and that there is not a pro-

gressive loss in weight with time, even when the specimens are subjected to heating and cooling cycles. This same tendency also was shown in examining the weight-loss data collected on samples of 0.15 C steel exposed for 15,000 hr. A further basis for the belief that there is stabilization of the surface of the corrosion specimen with exposure are results presented by White, Clark, and McCollam[7] on the analyses of the complex scale formed on the surface of unstressed furnace-heated corrosion samples.

Their analyses of the scale layers show that, in the case of the low-chromium alloys, there is an increase of as much as 40 to 50 per cent in the chromium content in the inner scale layer over that contained in the parent metal, while the alloy content of the outer scale layer is practically nil. This same condition was true where Mo and Si were present as alloying elements.

It is quite probable that a similar build-up of alloy-rich scale at the surface of steels subjected to high-temperature steam has a marked stabilizing influence on weight loss with exposure, as photomicrographs of the scale in steam-corrosion samples show that it is likewise of a complex nature.

The authors' statement, regarding the resistance of alloys containing more than 7 per cent chromium, perhaps should be more specific. A 12 Cr-2 Mo alloy steel, examined after 12,000-hr exposure to 1100 F, has shown a greater weight loss than C-Mo steel. The influence of alloy additions to low-chromium steels can be seen by comparing the penetration value obtained on 1.23 Cr, Alloy B, Table 9 of the paper, and that of the 1.25 Cr-Mo listed in Table 7 of the paper. Here, with the addition of aluminum, the weight loss in 500 hr was nearly doubled.

A. R. Mumford.[8] The authors of this paper and the Special Research Committee on Critical-Pressure Steam Boilers are to be congratulated on this contribution to the literature, concerning the occurrences of corrosion in water vapor at high temperatures.

The writer has long been interested in the corrosion of steel and iron exposed to steam and condensate at much lower temperatures, and the discussion which follows is largely influenced by the knowledge that, at low temperatures and pressures, the problem is exceedingly complex.

At first glance, if we assume that the reaction is almost solely that of the production of hydrogen, it may appear that the problem of corrosion under high temperatures is very simple, but a simple solution is exactly what we assumed at first in the study of corrosion of iron in contact with condensate. The writer feels that the paper should include some information on the analysis of the steam vapor supplied to the experimental corrosion chambers. It may well be that the contamination by oxygen and perhaps ammonia is so small that it will have no influence on the larger reaction, but a statement indicating the amounts of such gases originally present might well be included in the paper as a matter of record. We certainly are unaware of the solubilities of such contaminants in condensates at high total pressures and temperatures, and we are not aware of the effect on the reaction of such contaminants under these high-temperature conditions. Data on the composition of the condensate also might well be included for the record, even though the influence of any contaminants which might have been found cannot be evaluated at this time. Similarly, the gaseous phase over the surface of the condensate might indicate to future investigators more details of the action which took place within the chamber.

From a metallurgical standpoint, metallographic examinations of the specimens before and after exposure would have provided rather interesting information and might have made possible a full explanation of the differences in corrosion indicated by the weight losses. The writer feels that his experience in low-temperature corrosion makes it advisable to try fully to understand the mechanism of the reaction as soon as possible, in order to understand and explain the resistance of some materials under certain conditions of exposure.

It is assumed that the data presented in the paper, with particular reference to penetration of the specimen, are based on distributing the average weight loss over the exposed area of the specimen. If this assumption is correct, then the information differs only from other published information at low temperatures in presenting the total loss rather than a rate. Inches of penetration per year has been used as a rate figure for heating-system corrosion but, because of the duration of the tests reported in this paper, it might well be reported as a rate per 100 hr. The writer converted the average penetration, given in Table 11 of the paper, to average penetration per 100 hr and found that he could see more clearly the inferences drawn from the data than as presented with the total average penetration rather than a rate. The influence of the oxide coatings in slowing down the continuance of corrosion is clearly evident on the rate basis, as is also the indication of the minor significance of the cycle at which sudden cooling took place.

J. B. Romer.[9] Corrosion tests have always involved the problems incidental to the preparation of the surface of specimens, removal of the products of corrosion without marring or pitting the unattacked surface, as well as determination of the actual loss or damage sustained by the specimen.

The authors' data on surface preparation and on stripping of the oxidized surfaces clearly warrant the methods they have finally adopted.

Aside from their main problem, but nevertheless of great importance, are the data on inhibitors. This is a subject of growing importance both in research and in industry. The data, contained in Tables 1 and 2 of the paper, show that all inhibitors are not equally efficient; that the inhibitor should be selected in accordance with the acid to be used for stripping; that the efficiency of the inhibitor decreases with rise in temperature and may completely disappear if the temperature becomes too high. Of great economic importance is the fact that, beyond a critical point which varies with each inhibitor, increasing the amount of inhibitor used adds very little to its effectiveness.

The great resistance of certain alloys, such as Hastelloy, Stellite, Colmonoy, and Lamite, to oxidation by high-temperature steam may be of considerable value for certain applications. To date, these alloys either do not possess certain properties which make them suitable for steam generation, or else they are not commercially available in the required form.

Several important features have been proved by the authors, particularly:

1 The reduction in rate of oxidation with time because of the impenetrability of the oxide film, the thickness of which is increasing with time.

2 The sharp increase in rate of oxidation at certain temperature levels, notably at about 1100 F for low alloys, and at higher temperatures for the higher-alloy materials.

3 The effect of chromium in reducing the rate of oxidation. The effect of chromium is well shown by the authors in their Figs. 7, 8, and 17, the latter being at 1200 F. If we take the 1100 to 1350 F data from Fig. 8, and plot it in a manner similar to that of Fig. 17, the effect of chromium addition is outstanding. These data are presented herewith as Figs. 22 and 23.

Chromium improves the physical properties of steel in many ways, and low-chromium alloys have very definite fields of usefulness. The authors' data on steam oxidation indicate that, when the operating temperature is below 1100 F, the gain from chromium additions is not large. However, a great deal is

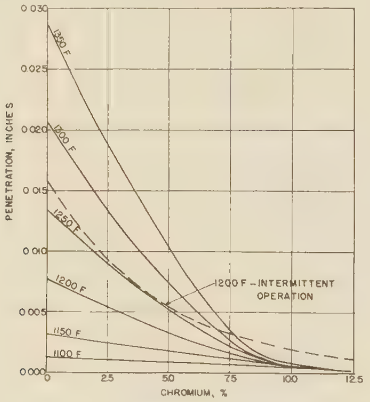

Fig. 22 Influence of Chromium Content on Corrosion of Steels During Steady and Intermittent Operation

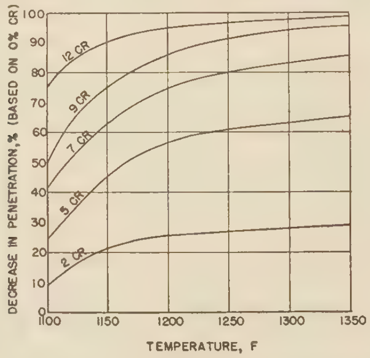

Fig. 23 Decrease in Penetration Vs. Temperature for Alloy Steels

gained by adding at least 7 per cent of chromium, whenever the operating temperature is in excess of about 1150 F.

The quantitative nature of the data presented by the authors will be of great value to those engaged in high-temperature high-pressure steam design.

Authors' Closure

The authors are indebted to Messrs. Clark, Van Duzer, Mumford, and Romer for their excellent written discussions.

The charts presented by Dr. Clark, which show the influence of silicon content on the oxidation resistance in steam and air and compare the corrosion resistance in steam and hot petroleum products, are indeed interesting and instructive. It is hoped that it will be possible to conduct additional tests which will throw light on the mechanism of attack in steam and air as suggested by Dr. Clark.

The close relationship between the authors' results and those of Fleischmann[10] is shown in the accompanying Fig. 24. Apparently Fleischmann found that the same general relationship exists between the decrease in penetration and increased chromium content as is reported by the authors. Mr. Van Duzer stated that tests conducted by him showed that the corrosion of 12 Cr-2 Mo was greater than for C-Mo steel after 12,000 hr exposure to steam at 1100 F. He further shows that 4-6 Cr steel corrodes more than 1.25 Cr-Moly between 2000 and 7000 hr exposure, and then less after 7000 hr. The authors had hoped that a complete report would be published of the extensive tests conducted by Mr. Van Duzer and his colleagues at The Detroit Edison Company. Since these tests were made on single specimens, the extent to which conclusions may be drawn from them would depend upon the consistency of the results. In the absence of complete data, it is rather difficult to compare results.

Mr. Mumford suggested the inclusion of water analysis and results of metallographic studies. A number of water analyses were made by Dr. Chittum of the Purdue University chemistry department. These analyses revealed that no ammonia existed and the oxygen varied from a slight trace to a maximum of 0.08 cc per liter. In any case, the possibility that oxygen influenced the reaction of the specimens with steam is probably very slight. Before entering the main reaction chamber, the steam first was passed through a gas-fired iron-tube superheater which raised the temperature to between 800 and 900 F. The chances that oxygen passed through this long tube without reacting with the iron of the tube are slight. If small amounts were able to escape the gas-fired superheater tube, reaction would then probably take place in the high-temperature superheater. Examination that the superheater tubing revealed that a small amount of corrosion occurred in the gas-fired tube and only a trace in the high-temperature superheater tube.

A large number of photomicrographs were taken during the course of the investigation to show any structure changes; however, these were not intended for use in publication and would not make satisfactory prints. These plates are available in the laboratory files for examination by anyone interested in them and show no evidence of structural change.

The plots of the test data submitted by Mr. Romer are very interesting and show the marked influence of chromium content on the corrosion resistance for various temperatures.

In conclusion the authors wish to thank all of those who have presented oral and written discussions for their interest, comments and constructive criticisms.

Theoretical Consideration of Power Loss Caused by Combustion Knock

By C. W GOOD,[1] ANN ARBOR, MICHIGAN

In this paper the author presents a theoretical analysis to show that the power loss accompanying combustion knock may be attributed to a mass vibration of the gases within the combustion chamber rather than to radiation. Equations are developed, based on perfect gases, to show that, on the basis of assumptions made, pressure rise with normal combustion is proportional to the quantity of charge burned and to show the loss in effective pressure caused by the vibration resulting from knocking combustion. The latter have been developed for both the Otto and Diesel cycles and the relative theoretical losses for the two cycles is indicated. The author indicates the effect of differences between actual and assumed conditions.

POWER loss has been an accepted corollary of combustion knock for many years. This loss has been attributed to radiation. A theoretical analysis shows that it is actually due to a mass vibration or reciprocation of the gases within the combustion chamber. It is now generally accepted that a momentary high pressure is generated in that portion of the chamber where the detonation which is the source of the combustion knock occurs. The combustion in this zone is so rapid that there is insufficient time for the pressure to equalize. The gases in this region undergo a mass expansion, compressing the other portions. The inertia of the gases causes those being compressed to be compressed beyond the equalization pressure and those expanding to expand below the equalization pressure, thus starting the mass vibration in the chamber. The energy of the vibration is not effective in pushing the piston outward and thus represents a power loss. In so far as these vibrations are damped out by friction within the gas itself, the mechanical energy of the vibration reverts to heat and becomes effective. However, such motion improves the conditions for conduction of heat from the gas to the chamber walls and this increase is loss which is chargeable to the cause of the combustion knock.

While exact measurement of the various factors is difficult, an analysis based on the laws of perfect gases is relatively simple and serves to demonstrate that not only does such a loss exist but that it can be quite appreciable. In order to arrive at the loss due to combustion knock, it is first necessary to formulate the conditions for normal or nonknocking combustion and then show, by a similar type of formulation, the effect of detonation.

To facilitate calculation, the following assumptions are made:

1 The gases behave as perfect gases.

2 The number and size of molecules is unchanged by combustion.

3 The specific heats remain constant with changes in either temperature or pressure.

4 The mixture is homogeneous prior to ignition.

5 The temperature is uniform prior to ignition.

6 All the combustion occurs in the flame front.

7 The process is adiabatic, that is, there is no heat transfer between the gases and the chamber walls and there is no radiation or conduction of heat between molecules, except in the form of work.

8 The energy liberated by combustion is constant, irrespective of the temperature at which it is liberated.

9 The chamber volume remains constant.

10 Detonation is complete before any expansion of the detonating portions occurs.

Obviously, none of these assumptions hold more than approximately for actual engines, but their use permits a simplification of the problem so that an analysis can be made which will help to explain the actual phenomena.

Fig. 1 shows a diagram of pressure vs. specific volume for the compression and combustion of specific portions of a charge in which certain portions burn normally, that is, at constant pressure, while other portions burn under detonating conditions, that

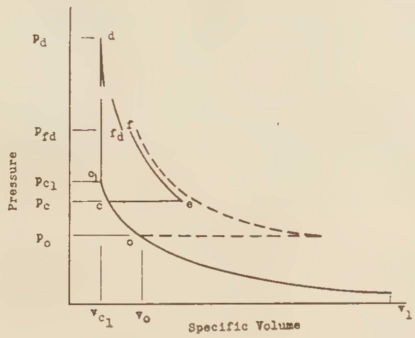

FIG. 1

is, at constant volume. The compression from 1 to *o* is accomplished by the piston. The piston is assumed to stay on top center until combustion is complete. The first portion is ignited at *o*, after which it expands during reaction along the horizontal dotted line. It is then compressed, as shown, by the other portions as they burn. As burning goes on, the portions remaining unburned are compressed adiabatically. *c* represents the point to which some specific infinitesimal portion is compressed when ignited. It then burns normally, expanding to *e*, after which burning of other portions compresses it along the adiabatic *ef*. When the pressure at which burning occurs reaches c_1, the remaining portions detonate. Their pressure and volume before expansion, based particularly on the assumption that detonation is complete before any expansion of the detonating portions occurs, is represented by *d*. They then expand along the curve df_d, compressing all the portions which had burned normally until the pressures of all the portions in the chamber have been equalized at a pressure, noted as p_{fd}, except for those variations in pressure caused by the mass vibration of gas.

On the basis of the assumptions made, the quantity of charge burned is proportional to the pressure rise with normal combus-

[1] Associate Professor of Mechanical Engineering, University of Michigan. Mem. A.S.M.E.

Presented at the National Meeting of the Oil and Gas Power Division, Kansas City, Mo., June 11–14, 1941, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

tion. This is shown by the following development. In Fig. 2, let the total volume of the cylinder be represented by v. Let the volume of a portion before burning, say the first tenth, be represented by v_b and the same portion after burning by v_a. During the burning of the first portion, the remaining portions would be compressed adiabatically from $v - v_b$ to $v - v_a$. The heat available as chemically stored energy in the volume of gas v_b may be represented by Av_b, where A may either be the British thermal units or foot-pounds of energy liberated by burning one cubic foot of the mixture at the original cylinder pressure. The heat liberation accomplishes two things: (*a*) Raises the internal energy of the portion of the gas in which the heat is liberated,

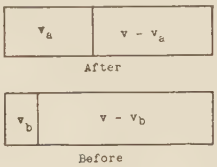

FIG. 2

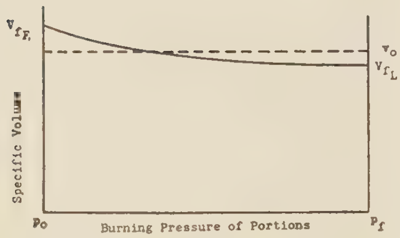

FIG. 3

which means raising its temperature; (*b*) does work on the remainder of the gases in the combustion space. Expressing this in the form of an equation

$$Av_b = dU_a + dW_r \quad [1]$$

where dU_a is the increase in internal energy of the burned portions and dW_r is the work done on the remaining portions.

$$dU_a = (p_a v_a - p_b v_b)/(k - 1) \quad [2]$$

$$dW_r = [p_a(v - v_a) - p_b(v - v_b)]/(k - 1) \quad [3]$$

By substituting Equations [2] and [3] in Equation [1]

$$Av_b = (p_a - p_b)v/(k - 1) \quad [4]$$

This is the typical equation for heat added at constant volume. The development shows, however, that with progressive combustion under the assumed conditions, the pressure rise is proportional to the quantity of gas burned. By letting $v_b = v$ in Equation [4], a relation is established between the mixture strength in terms of the heat available and the total pressure rise. This latter holds true only when the individual portions burn at constant pressure, that is, under what is here called normal burning.

Fig. 3 shows in a general way how the final specific volume of any infinitesimal portion varies with the pressure at which it starts to react.

Considering the diagram *ocef* in Fig. 1

$$v_f = (p_c/p_f)^{1/k} v_e \quad [5]$$

Using the general expression for heat added at constant pressure in terms of pressure, volume, and the ratio of specific heats k

$$Av_0 = p_c(v_e - v_c)k/(k - 1)$$

where A is in foot-pounds per cubic foot and represents the heat energy available as stored chemical energy in the mixture under the conditions of point *o*. From this

$$v_e = [A(k - 1)v_0/kp_c] + v_c \quad [6]$$

Also

$$v_c = (p_0/p_c)^{1/k} v_0 \quad [7]$$

By substitution of Equation [7] in [6] and then [6] in [5], v_f is found to be

$$v_f = p_c^{(1-k)/k} \frac{A(k - 1)v_0}{kp_f^{1/k}} + \left(\frac{p_0}{p_f}\right)^{1/k} v_0 \quad [8]$$

and Equation [4] shows that $(p_f - p_0)$ can be substituted for $A(k - 1)$ in Equation [8].

Since by assumption there has been no change in total volumes of the combustion chamber, the area under the curve v_f in Fig. 3 should be equal to the area under the dashed line v_0. This can be represented by

$$\sum_{p_0}^{p_f} v_f = (p_f - p_0)v_0 \quad [9]$$

The area under the v_f curve can be obtained from

$$\sum_{p_0}^{p_f} v_f = \int_{p_0}^{p_f} \left[p^{\frac{1-k}{k}} \frac{(p_f - p_0)v_0}{kp_f^{1/k}} + \left(\frac{p_0}{p_f}\right)^{1/k} v_0 \right] dp \quad [10]$$

and is found to prove the equality. Proceeding in the same manner, but assuming that the individual portions each burn at constant volume and expand, compressing the remainder of the charge, it can be shown that the equality expressed in Equation [9] does not exist, showing that the assumption of constant-pressure burning of the infinitesimal portions is correct.

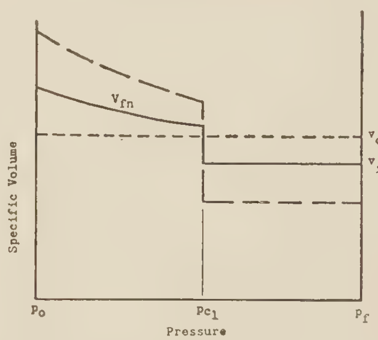

FIG. 4

In the case with detonation as assumed here, the final specific volumes of the respective portions burning normally will vary much as has been shown but the detonating portions will all have the same final specific volumes.

The variations are represented in Fig. 4. Here the full lines represent the final volumes at the equalized pressure while the dashed lines represent the respective specific volumes at the instant just prior to detonation. The dotted line is the specific volume of all the portions just prior to ignition. In Fig. 4, pressures were again used to indicate the portions burned. The final pressure with part of the charge detonating is not equal to the final pressure with normal burning, but is less depending on the proportion of the charge detonating, the compression pressure, the stored energy liberated by combustion, and the ratio of specific heats. The final pressure can be determined by integrating the areas under the v_{fn} and v_{fd} curves of Fig. 4 and equating the areas to $(p_f - p_0)v_0$.

$$\sum_{p_0}^{p_{c1}} v_{fn} + (p_f - p_{c1})v_{fd} = (p_f - p_0)v_0 \ldots\ldots [11]$$

$$\sum_{p_0}^{p_{c1}} v_{fn} = \int_{p_0}^{p_{c1}} \left[p^{\frac{1-k}{k}} \frac{(p_f - p_0)v_0}{k p_{fd}^{1/k}} + \left(\frac{p_0}{p_{fd}}\right)^{1/k} v_0 \right] dp$$
$$= [(p_f - p_0)(p_{c1}^{1/k} - p_0^{1/k})v_0 + p_0^{1/k}(p_{c1} - p_0)v_0]/p_{fd}^{1/k} \ldots [12]$$

In order to combine the second term of Equation [11] with the first, v_{fd} must be evaluated in terms of v_0. Referring to Fig. 1

$$v_{fd} = (p_d/p_{fd})^{1/k} v_{c1} \ldots\ldots [13]$$

$$v_{c1} = (p_0/p_{c1})^{1/k} v_0 \ldots\ldots [14]$$

For the constant-volume burning

$$A v_0 = (p_d - p_{c1})v_{c1}/(k-1) = (p_f - p_0)v_0/(k-1)$$

So that

$$p_d = [(p_f - p_0)v_0/v_{c1}] + p_{c1} \ldots\ldots [15]$$

And

$$v_{fd} = [(p_f - p_0)(p_0/p_{c1})^{(k-1)/k} + p_0]^{1/k} v_0/p_{fd}^{1/k} \ldots [16]$$

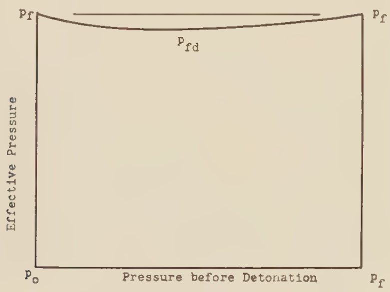

FIG. 5

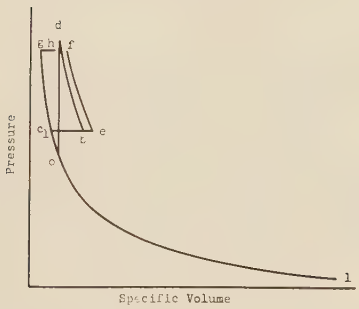

FIG. 6

Substituting Equations [12] and [16] in Equation [11] and rearranging terms

$$p_{fd} = \left(b^{1/k} - \left\{1 - \left[(a-1)\frac{1}{b^{(k-1)/k}} + 1\right]^{1/k}\right\}\frac{a-b}{a-1}\right)^k p_0 \ldots [17]$$

where

$$bp_0 = p_{c1} \text{ and } ap_0 = p_f$$

Fig. 5 shows the general nature of the variation of the final pressure with the pressure at which detonation occurs. It will be observed that, with one hundred per cent detonation, the final pressure is the same as with normal combustion. This is logical since all the portions are undergoing the same change at the same time.

In the case of the Diesel cycle the combustion knock occurs near the beginning of combustion rather than at the end as is the case with the Otto cycle just considered. In the actual combustion, some normal burning precedes the detonation responsible for the knock but, for purposes of this theoretical consideration, it will be considered as occurring at the beginning as indicated in Fig 6.

All the charge is compressed from point 1 to point o by the piston after which a portion detonates. Assume that the portion which burns under constant-volume conditions would, under

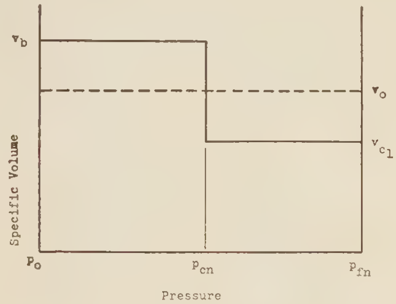

FIG. 7

normal burning conditions, have raised the pressure uniformly in the chamber to a pressure p_{cn}. It has already been shown in connection with Equation [4] that the pressure rise, with constant-volume combustion of the charge from point o, results from normal combustion of the charge, so the pressure p_d is equal to p_{fn}; the subscript n indicates normal burning. Now assume that the detonating portion expands so that the pressure of the unburned portion equals that of the burned portion, which is compressed.

Again using normal burning pressures to represent quantities burned, the specific volumes of the burned and unburned portions are shown in Fig. 7. The equalized pressure p_{c1} may be obtained by equating the areas under the v_b and v_{c1} lines to the area under the v_0 line.

$$(p_{cn} - p_0)v_b + (p_{fn} - p_{cn})v_{c1} = (p_{fn} - p_0)v_0 \ldots [18]$$

However

$$v_b = (p_{fn}/p_{c1})^{1/k} v_0$$

and

$$v_{c1} = (p_0/p_{c1})^{1/k} v_0$$

so that

$$(p_{fn}/p_{c1})^{1/k}(p_{cn} - p_0) + (p_0/p_{c1})^{1/k}(p_{fn} - p_{cn}) = p_{fn} - p_0$$

or

$$p_{c1} = \left\{[p_{fn}^{1/k}(p_{cn} - p_0) + p_0^{1/k}(p_{fn} - p_{cn})]/(p_{fn} - p_0)\right\}^k \ldots [19]$$

Letting $ap_0 = p_{fn}$ and $bp_0 = p_{cn}$

$$p_{c1} = \left\{[a^{1/k}(b-1) + a - b]/(a-1)\right\}^k p_0 \ldots\ldots [20]$$

Since the pressure rise caused by the portions burning normally is proportional to the quantity burned, the loss in effective pressure is $p_{cn} - p_{c1}$ and the percentage power loss is

$$L_D = (p_{cn} - p_{c1})/(p_{fn} - p_0) \ldots\ldots [21]$$

The power loss with detonation in the Otto cycle is

$$L_O = (p_{fn} - p_{fd})/(p_{fn} - p_0) \ldots\ldots [22]$$

In Fig. 8, the per cent power losses are shown for the two cycles

when a is taken as 4 and k as 1.3. Here it must be remembered that, in the case of the Otto cycle, b is a measure of the portion of the charge which burns normally whereas with the Diesel cycle it is a measure of the quantity of charge detonating.

Since, with the Otto cycle, the specific energy of the charge is inherently greater than that of the Diesel, the dotted curve is included to show the effect on the Diesel loss when a is reduced to 3.

All of the foregoing is based on the theoretical conditions assumed at the beginning and therefore cannot be expected to hold absolutely in practice. In the following an attempt is made to predict, on a basis of present knowledge, the extent to which actual combustion varies from the assumed theoretical conditions.

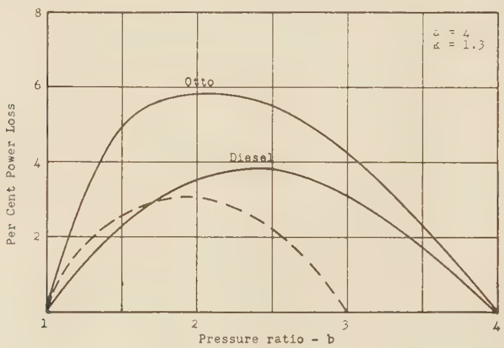

Fig. 8

The gases entering into the combustion do not behave as perfect gases. The principal difference of importance is the variation in specific heat with temperature and pressure. A study of the charts prepared by Hershey, Eberhardt, and Hottel[2] shows that in the ranges in which combustion occurs, k is in the neighborhood of 1.3. The equations show that the lower the value of k the less the loss for a given percentage of the charge detonating in either case.

Likewise the number and size of the molecules change. However, these changes do not affect the results appreciably. The mixtures are not homogeneous nor are the temperatures uniform prior to ignition. These, together with the fact that the reactions are known to be chain reactions, make it impossible to have all the combustion occur in the flame front. Recently published results by Withrow and Cornelius[3] indicate that as much as 30 per cent of the burning, under what are called normal burning conditions, does not occur in the flame front. Whether or not the same proportion holds for the detonating portions, in the time interval before the expansion of this portion becomes appreciable, has not yet been determined. This would cause an appreciable difference in either cycle.

The combustion process is not adiabatic, but in this case the lack of conformance tends to increase the power loss rather than decrease it, because the rapid vibration of the gases back and forth in the chamber is conducive to increased heat transfer to the chamber walls over that which would occur with normal combustion, where there is comparatively little gas motion, or that which would occur with one hundred per cent detonation. In all probability, the high radiation attributed to knocking combustion came from the chamber walls which were subjected to this high heat transfer from the rapidly moving gases.

[2] "Thermodynamic Properties of the Working Fluid in Internal-Combustion Engines," by R. L. Hershey, J. E. Eberhardt, and H. C. Hottel, *S.A.E. Journal*, vol. 39, 1936, pp. 409–424.

[3] "Effectiveness of the Burning Process in Non-Knocking Engine Explosions," by Lloyd Withrow and Walter Cornelius, *S.A.E. Journal*, vol. 47, 1940, pp. 526–545.

The chamber volume does not remain constant while combustion is in process; the change depends upon engine speed, and, in the case of the Otto cycle, affects the amount of detonation. One of the principal means of controlling detonation is to cause the latter portion of the burning to occur while the chamber volume is increasing.

Detonation is not complete before expansion of the detonating portion starts. In the case of the Diesel, where the detonating portions do not necessarily form one contiguous mass of gas it is quite probable that considerable such expansion does occur.

The fact that detonation probably does occur in disconnected masses of the charge in the Diesel probably promotes turbulence in the chamber. Professor Vincent[4] has advised the author that in his experimental work in the development of Diesel engines he has been able to improve efficiency with a small amount of detonation.

From these theoretical considerations it would appear that the cause of power loss with combustion knock or detonation is the vibratory motion set up in the chamber, and that the loss is represented by the kinetic energy of the vibration and the heat transferred to the chamber walls because of this motion. It also appears that the loss with the Diesel cycle is relatively less than with the Otto cycle.

Discussion

W. L. H. Doyle.[5] Referring to Fig. 8 of the paper, the writer is interested in the use of a value of 1.3 for the coefficient k. This value seems to be widely divergent from values developed from various test-engine indicator cards, particularly in the case of high-compression oil engines. For spark-ignition gasoline engines the indicator cards evidence values somewhat above the 1.3 value. Studies of indicator cards for high-speed high-compression oil engines evidence appreciably higher mean values of k, ranging from 1.37 to 1.43 for the expansion stroke. How are the somewhat different values of k, found in actual engines, reconciled with the author's mathematical treatment?

C. B. Rosenberg.[6] Do the author's assumptions on the Diesel-injection process, which to the writer is a sustained burning process, strictly substantiate his first assumption that there is a homogeneous mixture at the beginning of the combustion process. From observations made on work in the injection field, the writer feels that the primary charge of injection is perhaps the best example of homogeneous mixture which may be found, whereas the secondary and tertiary stages rather break down the first assumption that there is a homogeneous mixture.

Author's Closure

In consideration of Mr. Doyle's question relative to the use of a value of 1.3 for the coefficient k, it is necessary to differentiate between the expansion exponent n for the charge as a whole and the expansion exponent k for any infinitesimal portion of the charge. The former reflects a number of factors such as heat loss to the cylinder walls, blow-by, afterburning, etc., while the latter is understood to reflect only the ratio of the specific heats.

Considering these factors it is understandable that the value of n is appreciably higher than the value of k used in arriving at the data plotted in Fig. 8. The slope of the expansion line, on a log-log plot of the pressure-volume diagram for an engine, gives the value of n for any point on that expansion curve.

[4] E. T. Vincent, Professor of Mechanical Engineering, University of Michigan.

[5] Caterpillar Tractor Company, Peoria, Ill. Mem. A.S.M.E.

[6] Pure Oil Company, Chicago, Ill.

Such plots give values of n which normally vary from values less than 1 at the beginning of the expansion to values even above those given by Mr. Doyle, when afterburning has stopped and blow-by and heat loss to the cylinder walls are causing the temperature and pressure to drop more rapidly than would be the case with adiabatic expansion.

While k is supposed to reflect only the ratio of specific heats, it includes chemical-equilibrium effects at the high temperatures at which combustion occurs. The author has analyzed the Hottel charts to determine such values of k. Checking in the regions of high temperature and pressure, comparable with those existing in engines, values between 1.25 and 1.3 are obtained. Higher values of k would be obtained from the charts by extending the range downward to atmospheric conditions.

Due to variable specific heats alone k decreases with increases in temperature, and equilibrium effects just tend to make this decrease greater. However, it cannot within practical limits reach a value as low as 1.

Experiments on our universal test engine at the University of Michigan have indicated that the use of $k = 1.3$ for the calculation of the loss with detonation in an Otto-cycle engine gives results comparable with experimental results. In this connection, however, it must be remembered that the mass vibration of the gases in the engine produces a scrubbing action on the walls which offers an excellent opportunity, for heat transfer. The author is inclined to believe that the high radiation, reported by early experimenters who measured radiation through quartz windows in the combustion chamber, merely represented the increased temperature of the wall surfaces and not the increased gas radiation. We now know that temperatures with normal combustion may be as high or higher than those existing at any time in the detonating portions, so that the only factor which could contribute to the higher radiation would be the increased density of the gas. The heat loss, due to the scrubbing action of the gases on the cylinder walls resulting from the mass motion of the gases caused by the detonation, is attributable to the detonation.

The opinion has been expressed that these considerations are theoretical and some question has been raised as to their practicability. It is appreciated that this treatment is theoretical but, at the same time, it brings out certain fundamentals in the burning of the gases in engines which give a good indication of what is to be expected from the phenomenon called "combustion knock."

The writer has no experimental data to indicate to what extent the curves plotted in Fig. 8 are applicable for the Diesel cycle, but a check for the Otto cycle has already been cited. It may be pointed out that, in the work of Professor Vincent who has been concerned with the development of Diesel engines, it has been found that a slight amount of knock gives more efficient operation. This apparently is due to the increased turbulence in the combustion chamber, which helps to mix the fuel with the air.

As to Mr. Rosenberg's question regarding homogeneity, it is necessary to look at it from two standpoints. In the Otto cycle, it is questionable whether the incoming charge is thoroughly mixed with the products of combustion remaining from the previous cycle, so undoubtedly there is a certain amount of nonhomogeneity in the Otto-cycle engine. In the Diesel cycle, we know that it is necessary for the fuel vapor in infinitesimal portions to be associated with the oxygen within certain limiting ratios in order to secure combustion. As far as the infinitesimal portions are concerned, however, their behavior is much the same whether or not they burn in one flame front, as in the Otto cycle, or in one of the innumerable flame fronts existing in the Diesel cycle as combustion progresses. They undergo the same phenomena of compression prior to combustion, expansion during combustion, and compression following combustion, unless they burn during the detonating period in which period they have been assumed, in this study, to have no expansion during combustion. This is somewhat difficult to visualize, but the author trusts that it answers the question in regard to homogeneity.

Operation of Supercharged Engines in Pipe-Line Service

By J. B. HARSHMAN,[1] TULSA, OKLA.

This paper deals with some of the historical aspects of supercharging and the experiences of the Stanolind Pipe Line Company in the application of exhaust turbochargers, "Buchi" system, to four-cycle air-injection engines in pipe-line service.

History and Description of Supercharging Methods

The ambition of engineers and designers of Diesel engines for many years has been to build an engine which would produce more horsepower from a given cylinder size. The limiting factor (brake mean effective pressure) could not be raised above a certain point without encountering excessive operating temperatures, resulting in inefficient operation and high maintenance costs. Since most four-cycle engines were designed against inertia forces and not combustion forces, anything which increases the engine capacity by utilizing these oversized parts is an economic accomplishment; therefore, it was only natural that consideration would be given to mechanical means of charging the cylinders with air at pressures above atmospheric.

Some of the methods used to accomplish this are as follows:

1 Mechanically driven air pumps, mounted and driven from the main shaft of the engine or driven by rocker arms from the main crosshead assembly.

2 Belt-driven blowers, either centrifugal or rotary type.

3 Mechanically driven rotary-type blowers mounted directly on the engine frame and driven from the main shaft by gearing or chain.

4 The "Wibu" system, invented by two Polish engineers, Wicenski and Bujak. This system makes use of special intake cams and a tuned intake-piping system. The inventors claim from 25 to 40 per cent increase in engine horsepower.

5 The "tuned intake-pipe system" which provides for an intake pipe of the proper length to produce a natural oscillation frequency to coincide with the intake-valve opening. Thus, a certain amount of kinetic energy is produced, giving a ramming effect of the air in the cylinder.

6 The exhaust turboblower.

Certain claims are made for all of these methods. If an increased amount of air is provided, some results in the form of increased horsepower are to be expected. However, certain disadvantages were encountered with most of the methods mentioned which were undesirable, either from an operating or from an economic point of view.

Practically all direct-driven supercharging equipment comes in a similar category, i.e., it possesses certain undesirable characteristics, such as:

(*a*) The volume of air cannot be controlled to conform with load variation.

(*b*) A system of supercharging, producing only 15 to 20 per cent net increase in engine horsepower, cannot be justified economically.

The Buchi System

The Buchi system consists of a centrifugal air blower which is mounted on the same shaft with a single-impulse turbine, driven by the exhaust gas of the engine. The turbine and blower are mounted in the same case or housing with a system of labyrinth seals to prevent leakage from one compartment to another. The mean pressure on the exhaust gases ahead of the turbine is generally from 2 to 3 psi above atmospheric. The charging air from the blower is from 3 to 4 psi above atmospheric pressure. Extra-wide exhaust and intake cams are provided so that both exhaust and intake valves are open simultaneously, giving an overlap of 120 crank-angle deg.

While both valves are open, the charging air passes over the top of the piston, then through the exhaust valve. Thus, the cylinder is scavenged of burnt gases. The large volume of comparatively cool air, in passing through, to some extent cools the piston head, valves, and upper cylinder walls, and reduces the exhaust temperature. As the piston moves from upper dead center downward on the intake stroke, the cylinder is thoroughly charged with fresh cool air at pressures exceeding atmospheric.

Engines with four cylinders and over have a system of multiple manifolding of the exhaust to permit complete scavenging of one cylinder before the exhaust valve opens on another cylinder. Thus, overlap in the exhaust manifold is avoided. At the same time, efficient fluctuations or pressure waves are made use of in the exhaust manifolds to assist in scavenging the cylinders.

This division of exhaust manifolds is carried from the cylinders to the inlet of the turbine. Figs. 1 and 2 show typical arrangements for manifolding four- and five-cylinder engines.

Other than the division of the exhaust manifolds and the installation of larger inlet and exhaust cams, very few changes in the engine are required. The fuel system is adjusted to give a longer period of injection, the increase in the amount of fuel being proportional to the extra horsepower to be developed. The compression space must also be increased because of the higher pressure of the air at the beginning of the compression stroke.

The Buchi turbocharger can be set into the piping at either end of the engine at the height of the exhaust manifold, or it may be set on the floor and the piping extended from the engine to interconnect with the turbocharger.

Early Supercharging Experiments

Some of the first experiments in supercharging were made in Europe nearly 30 years ago. However, it was not until 1928 or 1929, that American engineers began to realize the possibilities of increasing horsepower satisfactorily by this method. The first commercial installation in the United States, of which the author has record, was made in 1928 by an American manufacturer in a Western state. The elevation of the plant was 9000 ft above sea level, and the engine was supercharged with a belt-driven rotary blower to produce its normal sea-level rating.

During the year 1930, another prominent American Diesel-engine manufacturer placed in service, in Middle Western States,

[1] Stanolind Pipe Line Company.

Presented at the National Meeting of the Oil and Gas Power Division, Kansas City, Mo., June 11–14, 1941, of The American Society of Mechanical Engineers.

two engines making use of belt-driven rotary-type blowers for supercharging. These engines were of the four-stroke-cycle single-acting type having a bore of $17^1/_2$ in., a stroke of 25 in., operating at 225 rpm. Both engines were used to drive alternators in municipal-plant service. The horsepower increase by supercharging was approximately 15 per cent.

About 1935, American Diesel-engine builders became interested in the accomplishments of certain European engine builders in the use of exhaust turbochargers. Early in 1936, several exhaust-turbocharger units were imported to this country for experimental purposes.

Since that time, numerous installations of supercharged engines have been placed in service, making use of the Buchi system. The majority of these are in locomotive service where maximum horsepower with minimum weight and space requirements are factors. There are, however, several stationary installations in use, two of which are in service on a major pipe line.

In the early part of 1936, the Stanolind Pipe Line Company was faced with the problem of increasing the pumping capacity at one of its trunk-line stations. The capacity desired was not sufficient to justify installation of an additional large unit; therefore, consideration was given to the possibility of supercharging one of the existing engines in the plant and increasing the speed of the pump by the installation of new gears of a lower ratio. Since the Buchi system seemed to have greater possibilities than other methods considered, an order was placed with the engine manufacturer for the turbocharger. The manufacturer also took the responsibility for doing the necessary engineering work and supplying the new cams, exhaust manifolding, etc., for the complete installation.

Experiences in Supercharging Pipe-Line Engines

In October, 1936, the company placed in service its first supercharged engine. The engine was a four-cylinder four-cycle type, having a 16.5-in. bore and 24-in. stroke, rated 400 hp at 200 rpm. The turbocharger was purchased for an increase of 25 per cent in engine output. The increased horsepower was accomplished without difficulty as far as engine troubles were concerned. However, trouble was experienced from the start with the ball bearings in the turbocharger. This turbocharger was built to operate at a top speed of 20,000 rpm, and operated at 15,000 to 16,000 rpm when carrying 500 engine hp. Apparently, the design of the ball bearings was inadequate for the thrust load to which they were subjected, and it was found that their life varied from a few hours to a maximum of 2000 hr.

Table 1 gives a comparison of the engine operating conditions when carrying 400 hp unsupercharged, with conditions prevailing when supercharged and carrying a 25 per cent increased rating.

TABLE 1 COMPARISON OF 400-HP ENGINE UNSUPERCHARGED WITH SAME ENGINE SUPERCHARGED AND CARRYING 25 PER CENT INCREASED HORSEPOWER

	Engine unsupercharged	Engine supercharged
Exhaust pressure at turbine, psi	..	2.45
Air pressure at blower, psi	..	3.31
Air-inlet temperature, F	..	50
Air-discharge temperature, F	..	105
Supercharger speed, rpm	..	15075
Injection pressure, psi	1000	1000
Compression pressure, psi	500	515
Maximum pressure, psi:		
1 Cylinder	590	650
2 Cylinder	650	650
3 Cylinder	700	650
4 Cylinder	600	650
Exhaust temperature, F:		
1 Cylinder	690	565
2 Cylinder	730	560
3 Cylinder	640	530
4 Cylinder	715	560

After about a year and a half of operation of this unit under a serious handicap, caused by bearing troubles in the turbocharger, during which time it was once returned to Switzerland for repairs, it was decided to ship the machine to an American engine builder and have the ball bearings replaced with sleeve-type bearings. During the period of tests on the supercharged pipe-line engine, this engine builder had placed several supercharged Diesel locomotives in service and had encountered similar troubles with the ball bearings. Sleeve-type bearings were then developed for the turbocharger, which had proved very successful on the locomotive engines. The ball bearings were replaced, in the turbocharger owned by Stanolind, with bronze sleeve-type bearings, after which the machine was again placed in service. Lubrication difficulties were then experienced with the new sleeve bearings, one bearing failing after 19 hr of operation. The bearing was replaced, the lubrication problem was corrected, and another test was started.

Tests Made on Turbocharger at Increased Loads

A 25 per cent increase in engine horsepower was satisfactorily obtained. However, by this time, other American engine builders were becoming interested in the possibilities of supercharging, and some tests had been made in which 75 and 100 per cent increase in horsepower had been reached. Because of the expense involved in such an installation, it was decided that supercharging could not be economically justified for a 25 per cent increase in engine horsepower. After consulting the engine builder, a decision was made to conduct tests using the same turbocharger for a horsepower increase of 50 per cent. Certain changes were made in the nozzle rings of the turbocharger to prevent exceeding the 20,000 rpm speed limit. This test was a failure due to insufficient capacity of the turbocharger, and the machine was subsequently badly damaged from overloading and overheating.

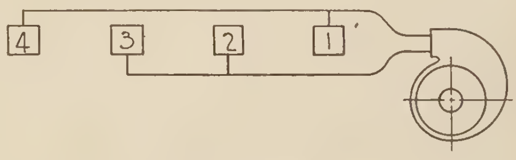

Fig. 1 Firing Order 1-2-4-3

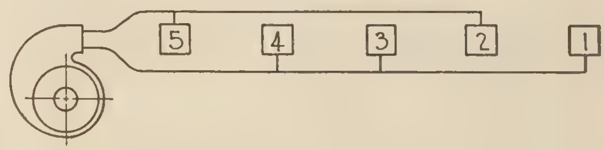

Fig. 2 Firing Order 1-3-5-4-2

Although many discouraging problems were encountered in the test of this first supercharged engine, sufficient information was obtained to convince all concerned of the practicability of supercharging, particularly by the Buchi method.

In August, 1940, the second supercharged engine was placed in service by Stanolind. This engine was of the four-cycle type with five $16^1/_4$-in. × $23^1/_2$-in. cylinders, having a normal horsepower rating of 500 at 225 rpm. In October, 1940, another turbocharger was placed in service on a 500-hp, five-cylinder, $16^1/_2$-in. × 24-in. engine. The Buchi system was used on both of these installations; however, the turbochargers were much larger machines with a full-load speed of only 12,000 rpm. Both turbochargers were equipped with babbitt-lined sleeve-type bearings. This equipment was purchased with the idea of increasing the engine output 50 per cent, or from 500 to 750 hp. The gear ratio was changed on the pumps, increasing the pump speed from 47 to

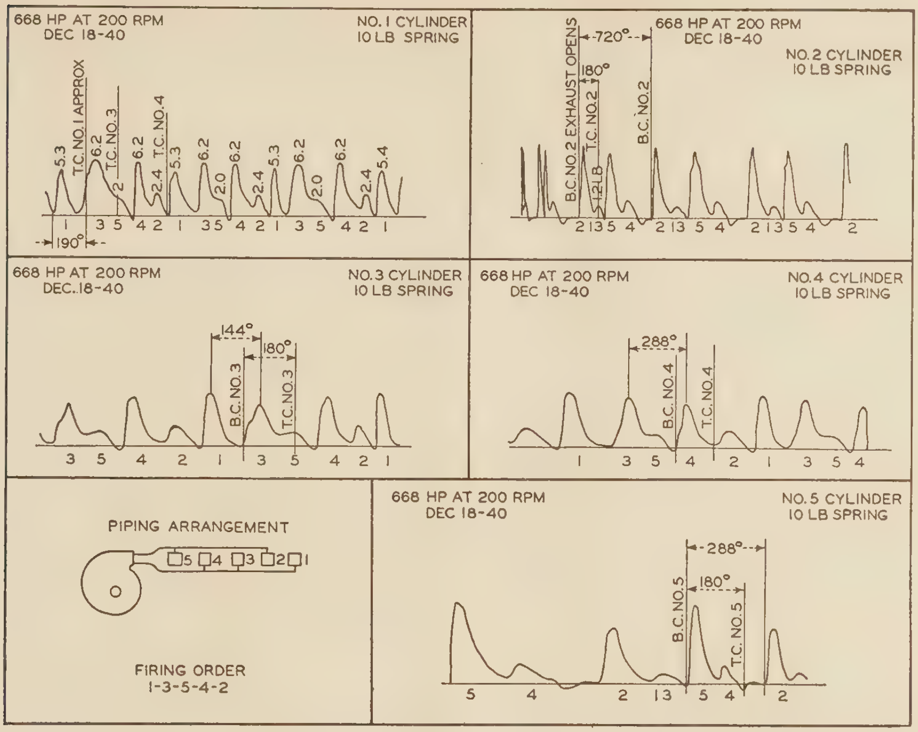

FIG. 3 WEAK-SPRING INDICATOR DIAGRAM TAKEN ON EXHAUST MANIFOLD; FIVE-CYLINDER ENGINE

55 rpm, in order to make full use of the increased horsepower. These units have been in continuous operation since that time. The only difficulty experienced is that the load balance cannot be maintained on the various cylinders of the engine because of overlap of the exhaust impulses in the three-cylinder manifold, as shown in Fig. 2.

Negotiations are now being carried on with the intention of developing a turbocharger with three openings in the exhaust-inlet casing for five-cylinder engines.

In Fig. 1, it will be noted that no two cylinders, exhausting into the same manifold, follow each other in firing sequence. In Fig. 2, showing the manifolding of a five-cylinder engine, it will be noted that Nos. 1 and 3 follow each other in firing order in the same manifold, which condition is unavoidable in a five-cylinder engine, unless three or more manifolds are used. Exhaust manifolds should be designed to prevent this condition; otherwise one of the cylinders affected by the overlap of the exhaust will not scavenge properly and will be overloaded.

Table 2 gives operating data on a five-cylinder, 500-hp, $16^1/_2$ in. × 24-in. engine supercharged with a double-inlet turbocharger. Fig. 3 shows hand-pulled indicator cards, taken at the exhaust nozzle of each cylinder on this engine, and also indicates the reasons for disrupted scavenging and overloading of the No. 1 cylinder.

TABLE 2 OPERATING DATA FOR FIVE-CYLINDER SUPERCHARGED ENGINE, DEVELOPING 668 HP, AT 200 RPM AND 102 BMEP

Exhaust temperatures, [a] F

No. 1 cyl	No. 2 cyl	No. 3 cyl	No. 4 cyl	No. 5 cyl
900	610	620	540	500
900	610	640	610	580
900	610	640	600	580
900	630	680	600	590
900	650	690	600	610

[a] Observed at different times during test.

From the measurements of weak-spring diagrams, shown in Fig. 3, it is reasonable to assume that the following back pressures at the middle of the scavenging period are approximately correct:

No. 1..............	4.5 Psi, with pressure increasing
No. 2..............	1.0 Psi, with pressure decreasing
No. 3..............	2.0 Psi, with pressure decreasing
No. 4..............	0.0 Psi, pressure curve level
No. 5..............	—0.4 Psi, pressure curve level

Air pressure at 665 hp = 3 psi

Pressure (mean) in upper exhaust pipe, 1.4 psi
Pressure (mean) in lower exhaust pipe, 2.0 psi

CONCLUSION

Sufficient experience has been gained from the installations described to prove that increasing the horsepower of existing pipe-line pumping installations is not only practicable, but economically justifiable. For instance, a 250-hp increase can be obtained by supercharging a 500-hp engine for an investment of approximately $12,500, including the cost of new gears for increasing the speed of the pump. This is equivalent to $50 per installed horsepower, which is less than one half the cost per installed horsepower when purchasing additional pumping units.

The use of supercharging has other advantages which make it attractive for pipe-line service. For instance, it frequently becomes necessary to provide a temporary increase in horsepower and pumping capacity at trunk-line stations handling oil from flush fields, or for a temporary peak load to certain refineries. After this peak-load requirement no longer exists, an engine which involved a large investment is usually left idle or operating at low capacity. If this peak condition is met by supercharging, the turbocharger and other equipment used in its operation may be moved at a nominal cost to another station, where the additional capacity can be used to advantage.

The only disadvantage actually encountered in the operation of the last two installations has been the inability to operate

these units at loads below the original rated horsepower of the engine. Although the exhaust-driven turbine is supposed to compensate automatically for load variation, it appears that an excess amount of air is forced into the engine for the quantity of fuel consumed, which results in poor combustion. After operating at reduced loads for a few days, it is necessary to remove the turbine rotor and clean out the carbon accumulations.

Our experience in the operation of the three turbochargers on pipe-line pumping units indicates that the following improvements should be made for maximum success:

1 The proper method of manifolding to prevent overlapping of exhaust from different cylinders.

2 Provision for some method of regulation of air at low loads to insure proper combustion.

3 The design of the turbocharger should be such that it can be installed in different positions to simplify piping and to permit adaptation to existing piping. The general appearance of present installations indicates that little or no thought has been given to obtaining a uniform and workmanlike piping job.

Regardless of the difficulties experienced with the first installation and the undesirable features mentioned, we believe that supercharging of Diesel engines for increasing the capacity of existing installations in pipe-line service has tremendous possibilities, and that its use will become general throughout the industry.

Discussion

C. W. Smith.[2] There is little doubt that turbochargers will be used to an increasing extent in the future for industrial applications. Heretofore, they have been used almost exclusively in the United States in conjunction with military-aircraft engines.

Although the title of this paper does not so indicate it is obvious that the author had in mind only the supercharging of Diesel engines. There is no reason why turbosupercharging should not be used also with Otto engines, but it is to be expected that the operating conditions will be somewhat different and that experience acquired with the Diesel engine cannot necessarily be applied to the more common Otto engine.

For instance, the engines mentioned by the author operated at speeds in the vicinity of 200 rpm. For engine speeds in the vicinity of 1000 or 2000 rpm, or more, it is not certain that the Buchi method of dividing the exhaust manifold will, of itself, be sufficient to insure complete scavenging and to give the same large percentage increase of engine output obtained at very low engine speeds. It will be necessary to insist on the highest possible turbine and compressor efficiencies and perhaps to operate with a somewhat higher exhaust-gas temperature. It might be pointed out that the Buchi manifold would not be necessary even at low engine speeds if the over-all efficiency of the turbosupercharger were high enough.

Another method of avoiding the divided manifold would be the use of a geared or belted compressor in series with the turbine-driven compressor. In certain cases, this might result in somewhat less complication than the Buchi system.

The author mentioned the disadvantage encountered in operating at light loads. If this is caused by a disproportionately large air flow, it should be possible to correct the condition by changing the characteristics of the compressor, or of the turbine, or perhaps of both, with a resultant improved specific fuel consumption, as well as better mechanical operation.

It is ordinarily considered that, when engine output is increased by the method described in the paper, a gain in fuel economy should also result, since the fixed engine losses are increased much less than in proportion to the increase in brake horsepower. The author makes no mention of this, and it would be interesting to know whether his experience verifies this expectation.

[2] General Electric Company, Lynn, Mass.

E. S. Thompson.[3] Because of the fact that the title is rather general and might be interpreted to include turbosuperchargers applied to Otto-cycle engines, it seems to be desirable to add something to the history of superchargers, as presented in the paper.

The supercharger development was a by-product of an effort to develop a gas turbine, the modern turbosupercharger approaching that machine very closely. The gas turbine is an apparatus for obtaining power from products of combustion which directly operate a turbine wheel. This has been a dream of engineers since John Barber's British Patent of 1791, which shows most of the modern elements. The mechanical resources of that period could never have produced an operative apparatus, and so the idea lay dormant for a hundred years. Then the steam turbine and the internal-combustion engine, independently, became successful means for obtaining power; so beginning about 1890, many people thought of combining the two, most of them supposing that they themselves had invented the gas turbine.

The earliest extensive use of the supercharger was made to obtain sea-level power from an airplane engine when flying at an appreciable altitude. The density of the atmosphere decreases rapidly with the altitude and the weight of charge to the cylinder, and hence the engine power decreases proportionately. A supercharger compresses the altitude atmosphere so as to restore sea-level density within the cylinder, and thus, sea-level power. Such a use of superchargers to restore sea-level conditions at altitude was soon extended to give increase of power of an airplane engine at sea level, called "ground boost."[4]

Supercharger investigations were in progress by the Allies prior to the entry of the United States into the first world war, with most of the activity centering around the turbo or exhaust-gas-driven type of compressor, the investigations being under the direction of Professor Rateau of France. M. LeBlanc of France was also investigating the possibilities of supercharging with an engine-driven device. The Germans were reported to be doing considerable work along this line, with most activities centered around geared units. Upon entry of the United States into the conflict, such information as had been obtained by the Allies on superchargers was made available.

The American Expeditionary Force, under the direction of engineering officers, endeavored to construct a geared supercharger for use in conjunction with the Liberty engine. Mechanical details, however, appeared to preclude the possibilities of a satisfactory development along this line. The need for great altitude performance was paramount, and the problem of developing a suitable supercharger was undertaken by the engineering division of the Army Bureau of Aircraft Production, with every effort being made to expedite the development. Available information on superchargers was so limited that an analysis was decided upon to ascertain the most satisfactory type of drive-and-compressor assembly, in which rotary, reciprocating, geared-centrifugal, and exhaust-gas-driven compressors were considered.

At that time, some 15 years ago, to interconnect the geared-centrifugal compressor to the engine satisfactorily was believed to be impossible, since operating gearing and bearings at speeds required to provide efficient units was not believed possible. The rotary and reciprocating types were discarded because of their bulk. Therefore, the combination of the exhaust-gas

[3] General Electric Company, West Lynn, Mass.

[4] "Superchargers," by S. A. Moss, *Aeronautics*, vol. 7, 1941, p. 2341.

turbine and centrifugal compressor appeared to offer more possibilities than any other type because of its compactness, simplicity, flexibility, and the utilization of the energy available in the exhaust gases. This particular supercharger incorporates a centrifugal compressor which must rotate at high speed to be effective, thereby creating an application for which the turbine is ideally suited. Two projects were then started, one under the direction of S. A. Moss of the General Electric Company, and the other a series of designs by E. H. Sherbondy, which were more or less in accord with the practice of Rateau in using an entirely enclosed turbine wheel. Although the Sherbondy design was dropped after construction of three models, it had a number of ingenious details. Thereafter, all work was centered around the General Electric design.[5]

The use of turbosuperchargers for airplanes has advanced tremendously in the last few years, and it is not too great a stretch of the imagination to predict that all airplanes in the not distant future will be propelled by engines equipped with turbosuperchargers. Application of the turbosuperchargers to truck and automobile engines also offers attractive improvements in power and performance.

R. Tom Sawyer.[6] The advantage of the turbocharger is that it may be installed on practically any engine, although it works more efficiently on some engines than on others. It is, of course, better to have the engine and the turbocharger built as a unit, thus correcting certain minor faults which the author mentioned, as, for example, the piping.

The matter of time lag in the functioning of the turbocharger was not mentioned in this paper. When a load is applied to the engine, a certain time lag occurs before the turbocharger becomes effective. In locomotive practice when the throttle is closed, the engine is idling; when the throttle is opened quickly the engine comes up to speed, but the turbocharger does not respond instantaneously; there is a lag of 3 or 4 sec. Oddly enough, for locomotive operation, that lag is advantageous, since it gives a cushion effect.

Each year, the writer's company compiles a complete statement of the cost of operating its Diesel locomotives. We have two classes of switching locomotives. One is a 660-hp locomotive which consists of a six-cylinder engine; the other is a 1000-hp locomotive which consists of exactly the same engine except for a different camshaft and the turbocharger. Recent figures indicate that the maintenance cost of the 660-hp locomotives, from 1 to 4 years old, is 28 cents per hr. The cost of maintaining 1000-hp locomotives, in service from 1 to 4 years, comes to 29 cents per hr. Thus, for all practical purposes if the engines are adaptable to superchargers of the turbo type, we can be certain that the maintenance on the turbocharged engines will not be appreciably greater per year than on the same engine not turbocharged.

J. P. Stewart.[7] The writer would like to comment upon the author's three conclusions as follows:

1 The difficulty experienced with overlapping of exhausts from different cylinders was with five-cylinder engines. Present practice, in so far as Elliott-Buchi turbochargers are concerned, is expected to eliminate this difficulty by insuring that no two cylinders exhaust consecutively into any one individual exhaust pipe.

2 Not being familiar with the specific installations discussed, the writer will not attempt to explain the reasons for unsatisfactory combustion at low loads. However, one of the outstanding and well proved features of the Buchi system of turbocharging is the fact that charging-air flow is automatically adjusted on engine-load variations, as can be shown from numerous published performance curves on several makes of turbocharged engines.

3 The basic design of Elliott-Buchi turbochargers is such that they can be assembled in a number of different positions, to make them adaptable to widely varying installation conditions. Considerable thought is devoted to securing as neat and compact a piping installation as possible in each case. Naturally, it is somewhat easier to meet this requirement on new engines, which are designed specifically for turbocharging, although we can refer to a number of instances in which an eminently satisfactory piping arrangement has been worked out for engines of standard designs.

There are numerous distinct differences between turbochargers being built for aircraft gasoline engines and those for the Buchi system on Diesel engines. In aircraft applications, the turbine operates on constant pressure, as contrasted to the pulsating pressure with the Buchi system. Further, aircraft units operate on considerably higher exhaust temperature, and have a lightweight requirement, as well as a much shorter life expectancy. Turbochargers for Diesel engines need not be as lightly constructed and, for most heavy-duty services, should have a life comparable with that of the engine itself.

W. L. H. Doyle.[8] The author's experience involves large slow-running engines, having relatively fixed speed-range characteristics, and which are supercharged by the exhaust-gas-driven turboblower. In choosing supercharging equipment initially, he had available two other types: the mechanically driven centrifugal blower and the mechanically driven Roots-type blower. For his particular application, thinking in terms of the speed range involved, the supercharger equipment he selected has many advantages. Thinking in terms of faster running engines where wide speed ranges are involved, many factors enter which introduce the question as to the best type of supercharger equipment to use. That this is so is evidenced by the appreciable amount of thought being given to this subject, particularly among research engineers.

One point mentioned in the paper is that, for the author's type of equipment, the larger volume of comparatively cool air supplied by the turboblower is in part allowed to flow through the cylinder, serving to cool, to some extent, the piston head, valves, and upper cylinder walls. This is accomplished by delaying the exhaust-valve closing, in order to overlap the inlet-valve timing by a considerably greater angle than is usual for the nonsupercharged engine. This is a feature considered important to the operation of the exhaust-gas-turboblower scheme of supercharging.

For the mechanically driven type of superchargers, use of considerably less valve overlap seems advantageous, and, for "dry pistons," measurements of piston temperatures at high brake-mean-effective-pressure loads for values of overlap from 34 to 140 deg showed a negligibly small change in cooling effect on the piston head over this range. The advantage in blowing an excess of scavenging air through the cylinder during this overlap period for the mechanical-drive scheme apparently centers on the one factor of cooling the exhaust valve. Viewed in the light of these considerations, a certain amount of experimentation yet remains to define clearly good overlap practice, particularly as applied to the mechanically driven type of supercharging equipment.

The author also points out that the fuel system is adjusted to give a longer period of injection. For the slow-running type of engine, particularly with the narrow speed range here involved, it is important to hold peak cylinder pressure to conservative values, primarily because of bearing limitations. Under these conditions, for increase in load, an increased injection period could be used. However, this introduces factors which tend toward limitations of power capacity and which are also reflected in less favorable fuel consumption.

In the data of test runs reported by the author, compression pressures under the nonsupercharged and supercharged conditions are shown as substantially the same value, indicating a reduction in compression ratio in the case of the supercharged-engine assembly. There is a definite tendency to adopt reduced compression ratios for supercharging. In wide-speed-range engines, speed and load have marked influence upon the compression pressures. In Table 3 of this discussion are shown test data, taken about 2 years ago in connection with an experimental engine assembly, operating on part load at 850 rpm, and equipped with an exhaust-gas-driven turboblower supercharging unit. In the case of this particular experiment, standard or nonsupercharged engine valve timing was employed, and the supercharged air was passed through an aftercooler. Attention is called to the increase in compression pressure from idling to the 150-lb bmep load condition. It is also interesting to note the corresponding increase in maximum cylinder pressures under the special conditions of this test.

TABLE 3 PART-LOAD TESTS ON EXPERIMENTAL SIX-CYLINDER $5^3/_4$-IN. × 8-IN. DIESEL WITH EXHAUST-GAS-DRIVEN TURBOBLOWER, STANDARD ENGINE COMPRESSION RATIO, AND VALVE TIMING

Engine speed, rpm	850	850	850	850	850
Brake horsepower	Idle	50.7	100.8	151.4	201
Brake mean effective pressure	0	37.9	75.5	113.4	150.4
Compression pressure, psi	560	625	645	690	775
Maximum pressure, psi	675	965	1050	1115	1175

A maximum cylinder pressure of 850 lb is approximately correct for the standard line of engines. The conditions under which the special engine tests, shown in the tabulation, were run were appreciably different from any of the conventional engine conditions because of the supercharging situation.

The historical reference in the paper to altitude installations brings up another point. In most altitude applications, effort is made to regain sea-level power at the altitude. The term "normalizing" has recently been used in this connection, and is an expression which seems aptly fitted to describe these special conditions.

The writer would like to ask whether the supercharged engine, reported in Table 1, is an air-injection engine?

The author brings out a point, in connection with observed operating conditions, which is at variance with our experience, where he mentions difficulties experienced with his engines when operated at light loads, a condition he concludes as traceable to excess air. It seems more logical to attribute the cause for this difficulty to ignition and combustion factors involved in the use of crude oil, the effects of which are probably not aided by the less favorable atomization conditions inherent in the air injection, particularly at light load, than to consider the difficulties as being due to excess air or high air-fuel-ratio conditions.

Will the author supply information on changes in lubricating conditions as between the engines operating nonsupercharged and when operating supercharged?

E. J. Kates.[9] The question of satisfactory performance at partial loads is quite important. It would be even more important in some other fields of application than in pipe-line service. The latter is characterized by operation at constant load for long periods of time. Load changes are known in advance, and when once made, continue for quite a while. On the contrary, in certain other fields of application, such as electric generation, load changes come on so fast that supercharger control must be quick and automatic. Poor combustion, resulting from an excess amount of air delivered by the turboblower, might be quite troublesome. The writer's experience confirms the author's as to the bad effects of excess air. The resulting poor combustion should not be blamed on the fuel for it is inherent in the design of many engines. If turbocharging, as now employed, causes excessively high air-fuel ratios when the load is suddenly reduced, it is a fault which should be corrected before turbochargers are universally applied.

In presenting this paper, the author stated that he intended to experiment with supercharging produced by ramming and tuning effects in the air-intake system. This would be worth while, because if ramming will do the job, it will have many advantages over any mechanical apparatus attached to the engine as an accessory. Such ramming schemes hold promise, because even low-pressure scavenging greatly increases engine power, and much of the beneficial effect of supercharging comes merely from cleansing the spent gases out of the clearance space with fresh air. This is within the possibilities of a well-designed ramming system.

[9] Consulting Engineer, New York, N. Y.

D. D. Cook.[10] The data previously submitted indicate that higher operating temperatures can be expected following the use of supercharging equipment. It would be interesting to know if the author's organization has encountered any new difficulties with piston rings, from the standpoint of increased cylinder wear, shorter ring life, etc. What combination of piston rings has rendered the most successful service in the Stanolind Company's supercharged engines?

R. D. Campbell.[11] Does the author's company follow the practice of selecting fuel from some particular batch of oil being handled, setting it aside in a tank to be used as fuel? That is a practice on some of the pipe lines.

G. F. Noltein.[12] About two years ago, the writer's company took an order for our first two supercharged engines for continuous 24-hr dredging service. The engines were eight- and six-cylinder units, $14^1/_2$ in. × 20 in., of 1200 and 900 bhp, respectively. At that time, market conditions made it impossible to get exhaust turbochargers of the necessary size in the available time, so we used, in accordance with the rest of the equipment, Elliott centrifugal blowers driven by synchronous motors.

Our tests indicated at once that the exhaust temperatures as measured gave us no criterion as to the temperatures of various engine parts, such as pistons, valves, etc., as they would vary with the same load, but with different amounts of air passing through cylinders during the scavenging period and mixing with the exhaust gas.

More accurate investigations with the aid of built-in thermocouples convinced us that, whereas, the valves were actually considerably cooler than in an unsupercharged engine, since all the scavenging air has to pass by them, the piston, piston rings, liner, and spray-valve tip were hotter. Our company would not consider building supercharged engines for continuous duty without improved cooling and, particularly, without oil-cooled

[10] Cooktite Ring Sales Company, Chicago, Ill.
[11] Shell Oil Company, Wood River, Ill.
[12] National Supply Company, Springfield, Ohio.

pistons (at least, if the engine is supercharged above 20 per cent of its original rating).

We also found that, if an engine is required to develop its full torque over a wide range of speed, a centrifugal blower mechanically connected to the engine or driven by a synchronous motor from the engine generator will not work out so well since with adverse exhaust conditions (pulsations), the impeller might more or less slip through the air, maintaining the pressure in the manifold which it is capable of developing at the respective speed, but without the assurance that the calculated amount of air is going to the engine. A metering device in the line would be necessary to indicate the exact amount of air going to the engine.

In this respect, a positive-displacement blower seems to be preferable, as it will automatically build up a pressure difference which will put all the air through the engine.

Although these engines have been in successful service about $1^1/_2$ years, it is felt that the investigations are far from finished and that we still have much to learn from them.

In view of our experience, the writer is not too certain whether or not his company would recommend exhaust-driven superchargers for such service as in dredges where full torque is required at variable speeds, in tugboats which have much maneuvering and accelerating to do, or in shovels, draglines, hoists, etc., unless definite provisions are made to restrict possible overloads lasting appreciable amounts of time at decreased engine speeds.

It has been mentioned that experiments for determining the best overlap on large engines are very expensive and require a long time to make. The writer's company has cut these items down considerably by using, in the test setup, special split cams in which one half can be displaced against the other to vary the resulting overlap as desired. This has permitted us to make up to four tests in one day.

Author's Closure

The first question brought up in the discussion concerns fuel economy. We do not have any information on the fuel economy of these supercharged engines. The author does not know whether all pipe-line companies follow the same practice. We have an abundant supply of fuel oil, for we burn the oil we pump. Therefore, we are not much concerned about fuel economy. There are no means available in our plants for making fuel-economy tests and, for that reason, the point was passed over. Our company is interested primarily in the possibility of getting additional horsepower at a reasonable price, to permit pumping more oil. The engines in question have a normal fuel economy of about 0.41 lb per bhp-hr. There is nothing to substantiate the claim, other than belief that the fuel economy is just as good supercharged, possibly a little better under full-load conditions, but much poorer under low-load conditions, which probably accounts for the carbon accumulations when operating at low loads.

Referring to Mr. Doyle's data, it is quite evident that the engine on which those tests were made does not lend itself very admirably to supercharging, since it operates with a high maximum cylinder pressure compared to low-speed engines. A maximum pressure of 850 lb is about 150 lb higher than the normal 225- or 300-rpm solid-injection engine. Most engines with which the writer is familiar carry about 700 lb maximum cylinder pressure. It is doubtful whether a supercharged engine carrying 1050 psi maximum pressure would operate satisfactorily.

Concerning the speed range of engines and the effect of speed variation on supercharging, that condition would be more pronounced in locomotive engines, dredge engines, and engines which require some maneuverability, but on a pipe-line engine, the speed is fairly constant. When there is occasion to change speed, it is done slowly, operation continuing at the same speed for several days. Normally, on pipe lines, the range of speed is from 25 to 30 per cent of the engine rated speed.

To the writer's knowledge, we have had no lubricating-oil problem other than on one particular job where oil was lost from the pressure system with which we lubricate the turbocharger bearings. As far as the writer knows, we have had no loss of oil from the engine system proper. We gain oil in the crankcases because oil is wiped downward from the cylinders.

In reply to Mr. Cook, we have experienced no trouble with piston rings. At the present time, 2 two-piece rings are fitted to each piston; the rest are standard miter-cut snap rings.

Mr. Noltein brought up the matter of excessive temperatures. We have suspected that there might be something to that also, but from some of the information brought out in the discussion, it would appear that others are operating at much higher brake mean effective pressures than we are which is reflected by higher exhaust-gas temperatures. We plan on supercharging about twelve more engines, most of them 500-hp units; and, eventually, unless unexpected trouble is experienced, probably three times that many. The temperatures on our supercharged engines are much lower than the temperatures which have been mentioned in the discussion, which, it is believed, is a much more desirable operating condition. For instance, in "Test Results With Under-Piston Supercharging,"[13] it is noted that the average exhaust temperature approached 1000 F. To the author this would seem to indicate they are not doing as good a job of supercharging as they think they are, for the simple reason that the exhaust temperature represents an overload caused by insufficient air. From the air pressure shown, the engines should have plenty of air, but the air temperature is such that the volumetric efficiency in the cylinders is greatly lowered. A great deal more supercharging could be done with one third the pressure, if the temperature were lower.

[13] Paper by E. S. Dennison and W. A. Morain, presented at the National Meeting of the Oil and Gas Power Division, Kansas City, Mo., June 11–14, 1941, of The American Society of Mechanical Engineers.

Pre-Exhaust-Gas-Pressure Measurements for Indicating Diesel-Engine Performance

By B. H. Jennings,[1] Evanston, Ill., and T. E. Jackson,[2] Bethlehem, Pa.

The pressure existing just before exhaust in a Diesel engine is shown to be significant as a means of indicating load adjustments in a multicylinder engine. This paper explains the theory and method used in obtaining these pre-exhaust pressures, along with the supporting data from an extensive series of tests. These tests were conducted at Lehigh University on both two-stroke-cycle multicylinder engines and a four-stroke-cycle single-cylinder C.F.R. test engine. Under definite known conditions of injection, timing, and compression ratio it was found possible to evaluate both indicated and brake horsepower in terms of pre-exhaust pressure. Experimental work in progress shows that the same method is applicable to spark-ignition engines.

Determination of the distribution of load among the various cylinders of a multicylinder Diesel engine during operation has always been a difficult and tedious operation. Yet such information is vitally important when adjustments have to be made on the engine to enable it to develop its required power without overheating in any cylinder or when attempting to better poor operating economy. Such things as improper balance of fuel-pump quantity to each cylinder, variations in injection timing for each cylinder, and variations in spray-valve performance are items which should be under control of the operator at all times. Yet because suitable instruments for quickly indicating maladjustments have not been available, many engines do not operate even near their peak performance.

Various methods of gaging performance of Diesel engines during operation have been investigated over a number of years. With the slow-speed engine, conventional engine indicators have performed meritorious service but the time consumed in indicating a multicylinder engine was long and under quick load changes variations were often not even detected. Analysis of indicator diagrams themselves also led to inaccuracies as the necessarily high spring pressures produced cards of extremely small size. With the advent of higher-speed engines (even above 400 rpm) the conventional indicator was no longer satisfactory. Most indicating devices for high speeds, such as the carbon-pile or piezoelectric, each with its necessary recording or indicating device, represent relatively inflexible and expensive devices primarily suitable only for laboratory research. Balanced-diaphragm indicators are equally laboratory devices.

Methods available merely for equalizing loads among engine cylinders have been somewhat disappointing except for relatively crude adjustments in the field. When the indicator has not been used, comparisons of exhaust-gas temperatures and examination of exhaust color and appearance have been the most common methods.

The exhaust-gas-temperature method seems at first to have great possibilities, but does not seem nearly so satisfactory after being given deeper consideration. According to theory, the products of combustion will have a definite temperature after expanding during the working stroke of the piston, however, the actual temperature of the gases entering the exhaust will depend upon three things. The first of these is the amount of fuel and air burned together in the cylinder, where under balanced running conditions the exhaust-gas temperatures will all be the same. The second is the amount of scavenging air flowing into each cylinder of a two-cycle engine, particularly one having a reciprocating scavenging pump; this is not necessarily, and usually is not, the same in each cylinder. The uneven cooling of the thermal elements due to different quantities of scavenging air will unbalance the temperature readings haphazardly. The third factor affecting the exhaust temperature of any one cylinder is the location of its exhaust-gas opening into the manifold, with respect to the common outlet. The opening closest to the common outlet, having more hot gases flowing past it than the others, will definitely show a higher temperature. Any attempt, then, to balance the cylinders by this method may result in an overload on one or more cylinders.

The second method has more of the personal element embodied in it than the other one, as it consists merely of letting the exhaust gases escape into the atmosphere at the will of the operator. If the color of the gases, that is, the amount of visible smoke, is the same for each cylinder, the cylinders are assumed to be balanced. When these gases are almost colorless, the engine is assumed to be working under the best possible conditions. This method was the most popular among the older Diesel operators, but it is not very satisfactory even for balancing and gives no indication whatsoever of the power of the engine.

The use of the release pressure for indicating load conditions in the cylinders of internal-combustion engines was first proposed by Joseph C. Groff,[3] who devised an instrument that effectively operated on this principle. In this paper the principle is explained and developed and the experimental program and data corroborating the idea are presented.

Theory of Pre-Exhaust (Release) Pressure

Fig. 1 shows an idealized Diesel-cycle diagram drawn on the P-V plane. Here A to B represents compression, B to C combustion, C to D expansion, D to A the sudden drop in pressure when the burnt gases are released at start of scavenging. The pressure at D is here called release pressure or pre-exhaust pressure. Consider the cycle $ABC'D'$ in which less energy is developed, the release pressure D' is also correspondingly less than D. The problem involved becomes this: Does the variation in release pressure bear a commensurate relationship to either the brake or indicated mean effective pressure of the cycle? The answer to this question is definitely affirmative in terms of the indicated mean effective pressure of the theoretical air-standard cycle and the data hereinafter presented also show experimen-

[3] U. S. Patent Reissue 20,303.

tally, under a variety of test conditions, that the relationship is definite and well defined in actual engines.

Carrying through a conventional air-standard analysis of the

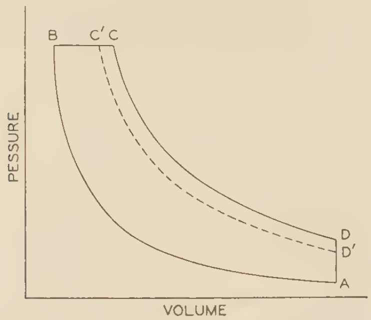

Fig. 1 Typical Theoretical Diesel Diagram

cycle $ABCD$ of Fig. 1 yields the following expression for the theoretical indicated mean effective pressure.

$$P_i = \frac{P_a r}{(r-1)(n-1)} \left\{ nr^{n-1} \left(\frac{P_d}{P_a}\right)^{\frac{1}{n}} - \frac{P_d}{P_a} + 1 - nr^{n-1} \right\} \ldots [1]$$

where P_a = suction pressure, psi
P_d = pre-exhaust (release) pressure, psi
r = compression ratio
n = polytropic coefficient of expansion or compression varying from 1.32 to 1.41 in value
P_i = indicated mean effective pressure, psi

This expression at first sight appears rather formidable but studied consideration shows that P_d is the only inherently variable term in the expression. The compression ratio r is fixed for a given engine, n is a function of cooling and scavenging conditions, and P_a, the suction pressure, is essentially constant for given engine and atmospheric conditions. Thus the release pressure is an index of mean effective pressure in this idealized analysis. If A, B, and C are constants for a given engine, Equation [1] can be written

$$P_i = AP_d \left\{ B \left(\frac{P_d}{P_a}\right)^{\frac{1}{n}} - \frac{P_d}{P_a} + C \right\} \ldots\ldots\ldots\ldots [2]$$

and in this form the relationship between P_i and P_d is more obvious.

That the air-standard Diesel cycle has pronounced limitations and does not represent any real cycle is realized by the authors but it does point to an existing relationship and indicates the feasibility of experimentally investigating the problem. This analysis also shows that the relationship will not be exactly linear between P_i and P_d but the actual release pressure will bear some definite relationship to the actual mean effective pressure.

Experimental Arrangement

The problem of experimentally measuring pre-exhaust pressure is the relatively simple matter of measuring the pressure which exists in an engine cylinder just before the exhaust valve opens in a four-stroke-cycle engine, or just before the exhaust ports are uncovered in a two-stroke-cycle engine. This merely involves making a connection through the water jacket, drilling a small hole through the cylinder wall, and tapping into place a connecting tubing to the outside. A typical design of a simple connection system which proved very satisfactory can be seen in Fig. 2, which is substantially similar to a conventional cylinder-lubricator connection.

It is also true that the position of the point of connection into the cylinder is not extremely critical. A study of Fig. 1 and of many actual indicator diagrams shows that just before D (or D') on the expansion stroke the pressure gradient per unit of piston displacement is rather small, consequently the point of placing the pressure tap can be moved up or down in the cylinder through the equivalent of an appreciable number of crank degrees without occasioning any significant change in the magnitude of the release-pressure values. It is only necessary that the tap point occur in the flattening portion of the expansion line reasonably ahead of the point of opening of the exhaust port in a two-stroke engine, or it must be uncovered by the piston in a four-stroke engine before the exhaust valve opens. In a given engine where relative evaluations of the output of each cylinder are significant, it is important that the tap points be placed at the same place in each respective cylinder.

To explain operation, as in Fig. 2, it can be seen that when the pressure in the cylinder is higher than in the pressure-gage chamber, a flow of gas passes through the check valve and a pressure build-up occurs while the tap is uncovered by the engine piston. After a few revolutions, the chamber pressure equals the then existing pressure in the cylinder during the period that the tap is uncovered, as the check valve keeps the chamber pressure from decreasing between impulses. To enable the release-pressure gage to follow decreases in load as the load and release pressure change on an engine, a slight leak-by opening is supplied. Thus, when the load decreases, the chamber pressure can fall until an equilibrium pressure comes into balance between the release pressure in the cylinder for that load and the pressure-chamber indication. This leak-by can be set to respond slowly or quickly and has been found to work satisfactorily for all conditions except very rapidly fluctuating loads.

This device was first tried out on a Bethlehem four-cylinder, single-acting, $8^1/_4 \times 12$-in. two-stroke-cycle Diesel engine. The engine used mechanical injection of the fuel, with a separate

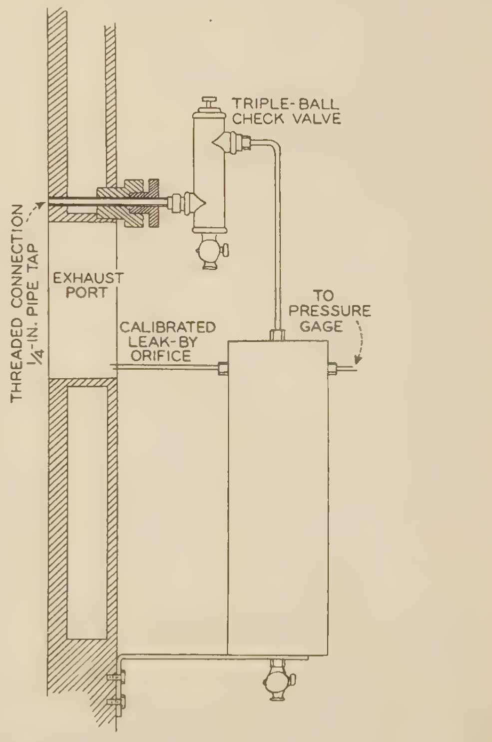

Fig. 2 Arrangement for Measuring Pre-Exhaust Pressure for a Two-Stroke-Cycle Diesel Engine

pump element for each cylinder, and employed by-pass control in the fuel pump for load variation. A separate cylinder supplied scavenging air at about 3 psi into a common scavenging-air header. The rated capacity of the engine was 120 bhp at 400 rpm. The output of the engine on test was absorbed and measured on a direct-connected Froude hydraulic dynamometer. Fig. 3 shows the engine with the release-pressure gages in place above and behind the cylinders.

It was difficult to obtain good indicator diagrams on this engine but a series of carefully taken light-spring diagrams on each cylinder showed a very close agreement between the release-pressure-gage readings and the release pressures as scaled from the indicator diagrams. The agreement was well within the closeness to which the release-pressure gages could be read. These gages were Bourdon-type test gages, with 4-in. face and a range of 0–60 psi. Under operating conditions of engine vibration they could be read to within 1 psi anywhere in their range.

A series of tests was then run in which the balance between the cylinders was thrown out by altering settings on the fuel-pump units. In every case it was found that adjusting the fuel-pump elements until the release-pressure gages on each cylinder read essentially the same gave a close balance of load for each cylinder. These adjustments were corroborated by using supplementary methods such as measurements of exhaust temperature for each

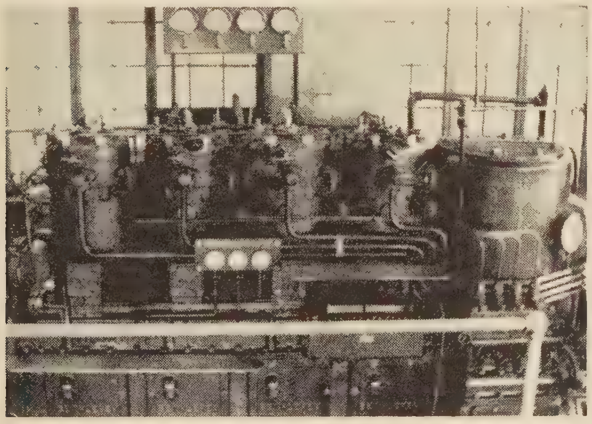

Fig. 3 Bethlehem Diesel Engine With Pre-Exhaust-Pressure Gages

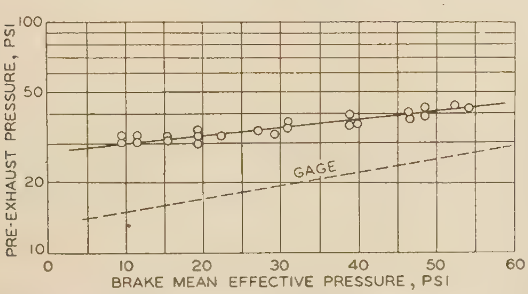

Fig. 4 Pre-Exhaust-Pressure Data—4-Cylinder Two-Stroke-Cycle Bethlehem Diesel Engine

cylinder by means of thermocouples; individual exhaust-color observations; measurements of jacket-water temperature; and, to a limited extent, by indicator diagrams. Over-all brake-horsepower tests, analyzed in terms of fuel economy with good and bad settings as indicated by the gages, also were indicative of the accuracy of this method for making adjustments.

It early became evident that a scientific analysis of release-pressure variations in terms of the variables of operation should be made on a one-cylinder engine so that individual effects could be singled out and evaluated. This was done, as is discussed later in this report, but certain of the data found on the four-cylinder engine also appear to be significant and are presented in Fig. 4. In this figure, the brake mean effective pressure is plotted against the release pressures averaged for the four cylinders. This shows a definite trend, as would be expected, but the points are more scattered than seems reasonable. The reason for this lies in faulty performance of the fuel-pump elements and of the injection system on this particular engine. Later investigation

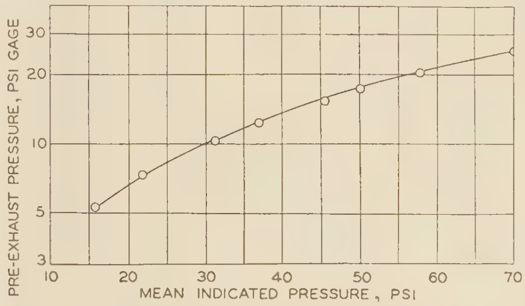

Fig. 5 Pre-Exhaust Pressure Data—Worthington Two-Cylinder Two-Stroke-Cycle Diesel Engine

showed 6-deg variation on injection timing of this pump. During the running period of certain tests the individual pump units frequently changed their settings and threw the individual cylinders out of balance. This tended to overload some cylinders and underload others and, it is believed, accounts for much of the scattering apparent on this curve. On the basis of the average data of this graph the following empirical equation, relating brake mean effective pressure P_b (psi) with release pressure P_d (psi gage), was derived

$$P_b = 7.08(P_d - 12.8)^{0.747}$$

Such a particular equation or plot applies only to a particular engine or engine type but when once found some idea of power output at a given speed would readily be available from the readings of a single release-pressure gage or set of such gages.

The next series of tests was made on a Worthington two-cylinder $12^1/_2 \times 13^1/_4$-in. single-acting, crosshead-type, two-stroke-cycle engine. This engine used the under side of each piston for compressing the scavenging air. Rated horsepower was 100 at 325 rpm. For test, the engine was loaded on a Froude hydraulic dynamometer and equipped with release-pressure equipment and gages similar to those described for the previously tested four-cylinder engine. The main reason for using this second engine was to find whether the generalizations found would hold for any engine, and secondly to check release pressures against indicated-horsepower readings. On this latter engine it was possible to obtain reliable indicator diagrams using a well-built, conventional piston-and-drum-type engine indicator.

The system of balancing loads between cylinders by release pressures was found to be satisfactory and reliable for this two-cylinder engine also and here it was possible to get indicator diagrams to corroborate the accuracy of the adjustments. It might be mentioned here that adjustments were also made to balance loading between the two cylinders by means of measurements of pre-exhaust-gas temperatures as well as the conventional measurements of exhaust-gas temperatures. Careful checks against indicator diagrams showed that release-pressure values checked the diagram values of mean effective pressure very closely at every measured point, whereas the exhaust-gas temperatures,

which showed a good index at medium load, appeared quite unreliable at full load on the engine.

The averaged results of a series of carefully run tests on this engine using release pressures and indicator diagrams is shown in Fig. 5. The lower three points on this curve were not taken from indicator diagrams because of the difficulty of precise interpretation of the light-load diagrams, but were computed back from carefully measured brake-horsepower measurements made during the tests.

The tests on both of these engines point to the conclusion that pre-exhaust-gas pressures can be used to indicate brake or indicated mean effective pressures when a determination of mean effective pressures in terms of pre-exhaust pressures has been made. Knowing these values and the revolutions per minute, the brake horsepower or indicated horsepower developed also becomes determinate. These tests also showed that this method was effective in balancing the loading among the various cylinders of an engine whether there was any real interest in horsepower evaluation or not. This latter item was more conclusively proved in the third series of tests using a single-cylinder engine. Both of the two-stroke-cycle engines tested were early-design units of low mean effective pressure and specific capacity as well as moderately low speed, however, there is no reason to believe that modern high-capacity and high-speed units would not perform similarly and this was found to be the case on the small four-stroke-cycle unit used in the third series of tests up to 1200 rpm.

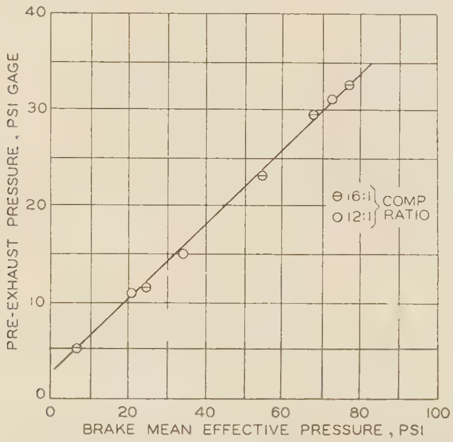

Fig. 6 Pre-Exhaust Pressure With Varying Compression Ratio

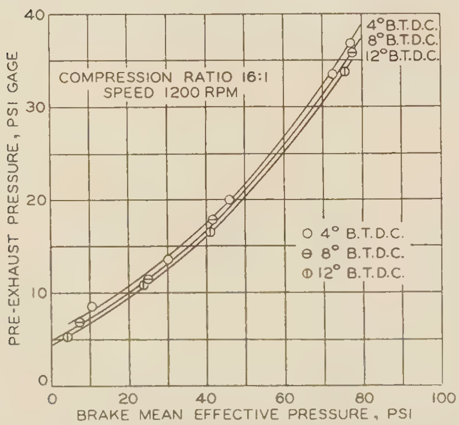

Fig. 7 Pre-Exhaust Pressure With Injection Timing Varied

The third unit used in these release-pressure investigations was a Waukesha standard C.F.R. Diesel fuel-testing unit. This unit was a $3^1/_4 \times 4^1/_2$-in. single-cylinder, four-stroke-cycle engine with provision for changing the compression ratio over wide limits, roughly anywhere between 7 and 30 to 1. For fuel-rating work the engine speed is maintained essentially constant at 900 rpm by a V-belt connection to a synchronous-type induction motor. For release-pressure work, however, the V-belts were removed and instead the engine was directly coupled to a cradled electric dynamometer so that precise measurements, control of power output, and speed variations could be made. The release-pressure connection, $^1/_8$ in. diam, was drilled through the cylinder wall at a point equivalent to eight tenths of the stroke down from top-dead-center position of the piston. This position for the release-pressure drilling was uncovered by the top piston ring just ahead of the time of opening of the cam-operated exhaust valve. Similar to the arrangements on the other engines, a three-ball spring-loaded check valve was connected as close as possible to the engine cylinder and a 100-lb, 4-in. Bourdon gage attached. A stop-cock relief was attached so that the pressure could be relieved and then allowed to build up before all accurate test readings were taken.

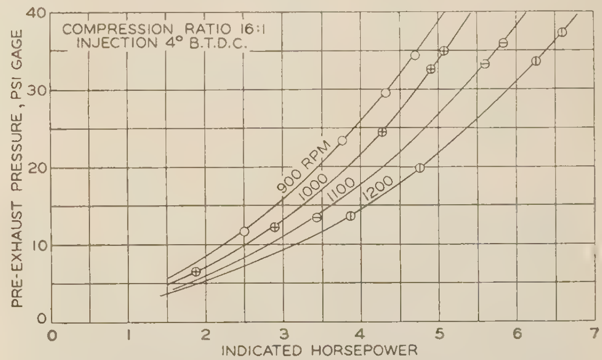

Fig. 8 Pre-Exhaust Pressure Vs. Ihp at Varying Speed

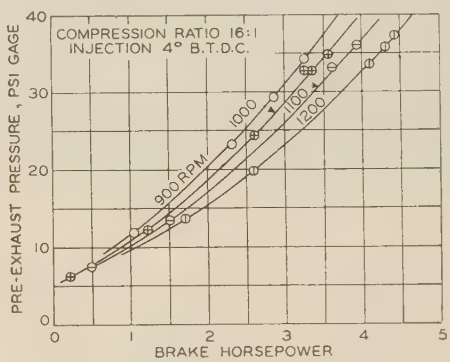

Fig. 9 Pre-Exhaust Pressure Vs. Bhp at Varying Speed

This unit has provisions for controlling and measuring both the quantity of fuel injected and also the time of injection. The cylinder-jacket water was kept at 212 F by evaporative cooling; and both lubricating-oil and air-supply temperatures were held constant within close limits. Indicator diagrams were not taken but numerous friction power tests were made by motoring the engine with the dynamometer, immediately following brake-horsepower tests and before thermal equilibrium had been lost by the engine.

Many tests were made on the engine in which speed, injection

advance, compression ratio, and fuel injection were varied. Space is available to record but a fraction of the data which were obtained and these are given in the curves of Figs. 6, 7, 8, and 9.

Fig. 6 shows a series of tests, in which the speed and injection timing were kept constant and the compression ratio varied. This series shows that for the range of compression ratios used, 12:1 and 16:1, the relationship of brake mean effective pressure and release pressure varies little with varying compression ratios, although for a given release pressure the value of brake mean effective pressure increases slightly with the higher compression ratios. This result was substantiated by additional tests at other speeds and compression ratios.

Fig. 7 shows the injection timing varied while compression ratio and speed are kept constant. Here, over the range investigated, for a given release pressure the brake mean effective pressure increases as the injection timing becomes further ahead of dead center. This trend also was confirmed at other speeds and compression ratios.

The effect of speed variations between the 900- and 1200-rpm ranges was found to be so small in relating brake mean effective pressure to release pressure that curves of this nature were not plotted. However, Figs. 8 and 9 are plotted to show release pressure in terms of indicated horsepower and brake horsepower with speed as the variable and with injection timing and compression ratio fixed.

Conclusions

All of these tests point to the fact that there is a definite value of release pressure which is related to the brake and indicated mean effective pressures being developed by an engine at a given time. In the case of two multicylinder engines it was also shown that using release-pressure readings as indexes for balancing and adjusting the load among the various cylinders was a simple yet effective method of control. The magnitude of release pressures in terms of brake or indicated mean effective pressures varies with each type engine, although these values should be the same for a given type of production engine. Three engines were tested, two of these were early-design two-stroke-cycle multicylinder Diesels and the third a single-cylinder four-stroke-cycle engine, of more recent design. Although release pressure showed a definite relation to brake mean effective pressure for each particular engine there is no relationship apparent between the three different engines. Maximum values for the three different engines showed 54 psi brake mep at 28.3 psi gage release pressure, 56 psi brake mep at 26.0 psi release pressure, and for the four-stroke engine, 80 psi brake mep at 35 psi release pressure. Even though release-pressure values did vary for these different engines, there is every reason to believe that this would not be true for a series of production engines but a given release pressure could be associated with a definite brake mean effective pressure, assuming that the gage attachments were properly made and operating conditions were essentially the same.

Discussion

C. B. Rosenberg.[4] Would the authors elaborate upon their description and function of the leak-by orifice which is incorporated into the instrument described? What effect would abnormal blow-by conditions have upon the results obtained with this instrument, that is, under conditions of instantaneously high blow-by rates at the time two or more piston-ring gaps are in line to allow leakage? Would the leak-by orifice compensate for such blow-by fluctuations? What effect would the presence of the increase in temperature, due to "hotter" blow-by gases gaining admittance into the "stabilizing" tank, have upon the gage reading?

[4] Pure Oil Company, Chicago, Ill.

E. J. Kates.[5] This method of measuring load conditions is interesting, and seems to have excellent possibilities. The writer would like to have the authors' opinions on the following questions:

(1) Is not this method subject to the same general faults as the method of checking load distribution by means of exhaust temperatures? In other words, if there are mechanical derangements of one kind or another in the individual cylinders, such as blow-by, do not the readings become unintelligible? One does not know whether a higher pre-exhaust pressure reading is caused by more load being carried in that cylinder, or by greater blow-by.

(2) What is the possibility of clogging occurring in the pipe lines which run from the cylinder connection through the tank and to the gage, due to oil and sludge accumulations getting into the lines?

(3) Has there been any trouble with corrosion of the gages due to the exhaust gases acting on the brass of the Bourdon tube?

Will the authors explain, if possible, the reason for the difference in curvature between the curves in Fig. 6 and Fig. 7 of the paper? Both charts seem to show pre-exhaust pressure plotted against mean effective pressure. In the case of the upper chart, Fig. 6, the relation seems to be that of a straight line, whereas the curves in Fig. 7 are all distinctly curved. Since the same relations are being plotted, why does the difference in curvature occur?

Referring to Fig. 5, it would be interesting to know, since this was a two-cylinder engine and the points plotted seem to be the average pressures of the two cylinders, what was the variation of the individual cylinder pressures? The curve of average pressures is quite smooth and the points seem to lie directly on it, but did the individual pressures of the two cylinders also come close to the same curve?

H. E. Degler.[6] Did the authors attempt to use pressure snubbers at the bottoms of the gages?

The writer is somewhat intrigued over the volume of the accumulator tank, as compared to the size of the orifice used, and as compared to the size of the connecting tube. Possibly, the word "volume" should be used for the connecting tube because the length is quite a factor, as well as the diameter, and also that other relation which, of course, would have to be the cylinder volume at the time this point is reached, as the piston moves downward. The writer believes there is some interrelationship between these volumes. This matter was not dealt with in the paper.

Do not speed of the engine and the inertia factors of the column of gas, as well as the possible, should we say, inefficiency of the check valve to function as effectively at all times and at all of these speeds, influence the curves given in the paper? Having a speed range of 400 to 1200 rpm, the writer believes there is something in that particular phase which might affect the curvature of the speed versus exhaust pressure and the mean effective pressure versus exhaust pressure. So it is his opinion that the insufficiency of the connecting device, as well as the column, etc., have something to do with the relationship of the quantities.

It would be of interest if the authors' experimental work could be continued on engines of higher than 1200 rpm, and also on engines with smaller cylinders; in other words, moving on into the more interesting and intricate range of speeds, smaller diameters, and,

[5] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[6] Professor of Mechanical Engineering, University of Texas, Austin, Tex. Mem. A.S.M.E.

let us say, a greater variation of the adaptability of this very unusual method of pre-exhaust-pressure indication.

J. C. Groff.[7] Having been indirectly associated with the authors in their work at Lehigh University in this new field, the writer appreciates what care and time were devoted by them to these tests and to the preparation of this paper and wishes to compliment them upon their presentation.

The writer's work on this development has been directed to the making of test installations on various types of engines operating under commercial conditions ashore and aboard ship. Naturally, this has involved considerable attention to detailed design for eliminating those "bugs" which always come into the picture.

To begin with, the apparatus involved in adapting this power-indicating principle has been termed "Load-I-Cator" for the reason that one of its chief functions is to indicate the "load balance" among the respective cylinders of a multicylinder engine. Now at last, internal-combustion-engine cylinder performance can be continuously gaged just as an electric motor is by a power meter. The instrument is designed to afford knowledge of instantaneous mean indicated pressure and mean effective pressure values indirectly by directly indicating "pre-exhaust pressure" or "pep," for short. Thus mean indicated pressure and mean effective pressure have acquired a new associate whose function it is to keep them balanced among the cylinders and so pep up their effectiveness by avoiding operation of inefficiently overloaded and underloaded cylinders.

Like many technical developments, this had its inception (in 1924) as the result of an engineer's laziness and desire for an easier way out. Being engaged on experimental and performance-test work ashore and as an operating engineer aboard various Diesel ships, one of the writer's jobs was to take a considerable number of indicator cards and then planimeter and figure them. Too often, this was done primarily to check the load balance, as indicated by the exhaust-gas pyrometers. This experience soon proved how unreliable pyrometers are for load balancing, and the work of indicating the engine was sufficiently bothersome and time-consuming to inspire developing something better.

From the thermodynamics involved, it seemed logical to suppose that there must be some reliable relationship between the amount of fuel injected, the amount of power developed, and the pressure to which the products of combustion are reduced at some single given point of piston travel, as indicated by a corresponding point on the expansion curve of the card.

Analysis of numerous indicator cards from various types of Diesel engines supported this supposition and showed that, subsequent to about 15 per cent of the power stroke, the pressure ordinate on the expansion curve varied in relationship with the mean indicated pressure developed at all corresponding single points of piston travel up to that of exhaust commencement. At from about 35 to 40 per cent of the power stroke, the corresponding cylinder pressure would almost indicate the mean indicated pressure directly in a 1-to-1 relationship. The next even relationship occurs at about 65 to 75 per cent of the power stroke where the cylinder pressures indicate about one half of the mean indicated pressure values in a 1-to-2 relationship.

As will be understood, the exact points of piston travel where the afore-mentioned even (mip/pep) relationships exist will vary with different types and sizes of engines, as well as with engine speed, due to correspondingly different heat losses which influence the shape of the expansion curve. However, once this point is determined from the indicator cards of a given engine, it remains practically fixed and can be used with reasonable accuracy for rapid checking of mean indicated pressure values from new cards. Also it is the same for all the cylinders of that engine. To so check new cards, it is only necessary to scale the pressure ordinates of the cards using a scale graduated in a 1-to-1 or 2-to-1 ratio to that of the particular indicator spring, depending upon which gaging point is used.

The next logical step was to so equip an engine that an indication of the cylinder pressure at some such point would be automatically and continuously available from each cylinder at all times. Doing this simply involves provision of a small port (i.e., $^1/_8$ to $^3/_{16}$ in. diam) in the side wall of the cylinder, to be uncovered by the top edge of the top piston ring at the proper point of piston travel, whereby the timing action is automatically taken care of. As described in the paper, the intermittent pressure pulses are translated into a self-adjusting sustained pressure, corresponding to that instantaneously existent in the power cylinder when the gaging port is uncovered, and this pressure is indicated by a conventional Bourdon-tube gage.

This led to the question as to where would be the most desirable point of piston travel for location of the Load-I-Cator gaging port. If the 1-to-1 ratio point were to be used, it would mean locating the port in the region of higher cylinder pressures and temperatures. Furthermore, the only advantage of so doing would be to obtain a 1-to-1 ratio so that the indicated cylinder pressures would read directly as mean indicated pressure values. Against this one dubious advantage were a number of compelling advantages in favor of locating the gaging port as near the exhaust point as practicable. These advantages have been proved valid from experience and are listed as follows, since they have an important bearing upon the successful operation of this scheme:

1 The nearer the exhaust point, the lower is the cylinder pressure and the temperature of the gases. This is of importance to avoid carbon formation in the gaging port, the check valve, and the connecting tubing.

2 The nearer the exhaust point, the more nearly does the expansion curve approach the horizontal and vice versa. Thus, near the exhaust point, reasonably small inaccuracies as to location of the gaging ports in the various respective cylinders of an engine have insignificant effect upon the accuracy of the cylinder-pressure indications. This will be apparent by merely comparing the slope of the expansion curve of any Diesel indicator card at about 35 per cent of the stroke with the slope near the exhaust point.

3 The nearer the exhaust point, the more nearly have the combustion gases expanded toward atmospheric pressure. Thus, at this point compression-ratio variations in the respective cylinders of an engine have the minimum effect on the cylinder-pressure indications.

The question has been asked whether difficulty has been experienced because of carbon formation in the cylinder-wall connection and the triple-ball check valve used. The answer is: None whatever; and the reasons will be more or less obvious when mentioned. To begin with, the teaching of the Load-I-Cator principle is to handle the cylinder gases near the exhaust point, where their pressures and temperatures are lowest; and, since the cylinder connection traverses the water jacket, near the comparatively cool water-inlet point, its temperature is such as to inhibit carbon formation. Furthermore, enough lubricating oil from the cylinder walls finds its way through the small bore of these cylinder connections to keep soot particles in a state of flocculent fluidity.

To anticipate the question which may occur to some readers, relative to the impairment of cylinder lubrication through the small loss of lubricating oil via these cylinder connections, as referred to, such doubts may be settled by repeating that the bore of these connections is only $^1/_8$ to $^3/_{16}$ in. ID. Thus, the amount

[7] Development Engineer, The Aldrich Pump Company, Allentown, Pa. Mem. A.S.M.E.

of cylinder oil to be lost thereby is insignificantly small compared to that lost through the much larger exhaust ports of two-cycle engines.

In the early stages, it was believed that an ordinary spring-loaded ball-check valve would be suitable for this purpose, but it was found that the spring superimposed a pressure-differential condition which produced erratic pressure indications under different engine speeds and load conditions. Using a free-ball check having a single ball, eliminated this condition; but occasionally, and too frequently for reliable results, a particle of soot would lodge between the ball and its seat and the pressure indication would gyrate. The solution arrived at was a triple-ball check valve with the idea in mind that the possibility of all three balls being so unseated at any one time would be highly remote. This has been proved in service.

Following the initial tests at Lehigh University and coincident with their subsequent test work, as covered in the paper, Load-I-Cator equipment was fitted to certain different types of two-cycle and four-cycle engines and subjected to continuous operation under actual service conditions for periods ranging up to more than 2 years to date. This was done to prove the principle and the ability of the equipment to operate successfully under nonlaboratory conditions, as must be faced in the field, before placing it on the market.

As a result of these tests at Lehigh and in the field, the apparatus has been developed and proved to the point described and illustrated.

The Load-I-Cator cylinder connection is much like a conventional cylinder-lubricator connection, in that it traverses a simple stuffing box screwed into the jacket wall and that its inner end is tapped into the liner wall (usually with a $^1/_8$-in. I.P.S. thread). The triple check valve is small in size and has a union connection with the cylinder connector. It is fitted with an inlet strainer which may be readily cleaned at periodic intervals by merely opening a pet cock while the engine is in operation. Incidentally, this pet cock affords the ideal method for obtaining true samples of exhaust gas for purposes of analysis.

Connected to the outlet from the check valve is a small pressure chamber. This vessel is mounted vertically and its upper portion serves as a receiver of sufficient volume to cushion the pulsating effects from the intermittent pressure pulses. The lower portion of this chamber is filled with a light grade of lubricating oil which serves as a seal between the corrosive gases and the Bourdon tubes of the pressure gages. The internal volume of this chamber is only about 4 cu in., which is sufficient for most engine speeds above about 350 rpm. For engine speeds below about 350 rpm, an auxiliary cushion chamber, having a volume of approximately 50 cu in. is interposed between the check valve and the afore-mentioned combination cushion-oil-seal chamber.

The question has been asked whether any special pressure-snubbing device is necessary to prevent the pressure gages from pulsating. The answer is yes; and a very simple snubbing device is incorporated in the aforesaid cushion chamber which eliminates all gage flutter.

A question has been asked as to the construction of the leak-by orifice, referred to in the paper, and provided for the purpose of equalizing automatically the pressure on the gages to that existent in the cylinder, in order to accommodate decreasing pressures for decreasing loads. This orifice is very simple and foolproof. As may be noted from its appearance, it consists merely of a stainless-steel pin located within a drilled hole, to provide an annular leak-off orifice of desirable small capacity yet without requiring a drilled hole of microscopic size. A glass-wool filter ahead of this orifice protects it against foreign matter and, should it become clogged, it is easily cleaned merely by moving the pin back and forth in its hole.

Since most stationary and marine Diesel engines are started by means of compressed air, the air pressure in each power cylinder, at the point where the Load-I-Cator gaging port is uncovered, may exceed the range of the pressure gages. Accordingly, to protect these gages from overpressure, each cushion chamber is equipped with a small spring-loaded relief valve. This valve may be so adjusted that it will relieve and whistle an alarm whenever the pre-exhaust pressure exceeds its normal full-load value. Thus, each cylinder is equipped with an overload safety alarm which will also indicate instantly the existence of piston-ring blow-by. For wholly automatic installations, this overload indicator may be used to actuate conventional safety controls to reduce the fuel supply, or to stop the engine just as do cooling-water-temperature and low-lubricating-oil-pressure safety devices.

With further reference to location of the pressure-gaging port, it will be obvious that the first requirement is that the top piston ring uncover it prior to commencement of exhaust. This means that the gaging port must be located above the top edge of the exhaust port on vertical two-cycle engines and ahead of the point of piston travel where the exhaust valve commences to open on four-cycle engines. The amount of lead or advance opening is governed largely by the engine stroke, speed and design of the piston as regards closeness of its fit in the cylinder, distance between the top ring and the top outer edge of the piston, etc. All of these factors have an important bearing and, for best results, the details of each prospective installation should be referred to the manufacturer of this patented equipment.

In order to minimize the pressure-build-up time in that part of the system, between the entrance to the gaging port and the triple check valve, it is made as compact in volume as possible. For this reason, the check valve is connected closely adjacent to the cylinder. As an example of how accurate the pressure indications are by this method, it may be mentioned that on a special test for this purpose the Load-I-Cator gage showed 23.0 psi, whereas scaling a light-spring pressure indicator card at the corresponding point of piston travel showed 23.3 psi, a difference of 0.3/23.0, or only 1.31 per cent.

Although not mentioned in the paper, being outside its scope, the Load-I-Cator performs another unique and important function in that it also affords a continuous check on the operating efficiency of the piston rings. This is done by indicating the existence of ring "blow-by" causing the pressure gages to read higher than normal. A gage reading which is somewhat higher than that proper for the maximum cylinder load indicates that the first or "fire" ring is stuck fast in its groove or otherwise improperly contacting the cylinder wall, to permit cylinder pressure to work down to the top of the second ring. Thus, under such conditions, the gaging port is uncovered earlier by the second ring and, in effect, at an earlier point of piston travel where the cylinder pressures are higher. Similarly, if the second ring is stuck or blowing-by, the gaging port is uncovered still earlier by the third ring and a still higher gage pressure shows up.

Since these pressure additions come in increments and since such overpressure can only result from ring blow-by, the indications can be relied upon. As an illustration of this, about 4 months after the first commercial installation went into operation, the engineer telephoned the writer to say that one of the Load-I-Cator gages on his two-cylinder engine showed an increase of about 25 psi since starting the engine following an overhaul. The answer to him was that the piston rings in that cylinder must have been changed and were not yet properly worn in to prevent blow-by. It required about 4 days of subsequent operation for the new rings to adjust themselves, during which time the high gage reading gradually came back to normal and stayed there.

In this connection, it is difficult to state which is the more important function of this device; its ability continuously to indicate accurate load balance, or its tell-tale indication of piston-ring blow-by, with the objectionable effects which are all too familiar. This would seem to be another of those "modern conveniences" which might be extolled at length without convincing one who is unfamiliar with it but which is quickly deemed invaluable by the operating engineer once he has it.

A. F. Robertson.[8] The writer is not familiar with any work of a similar nature to that described in this paper. There is one point of concern, however, and that is the maximum pressures in the engine cylinder. The engine has to be designed to run under certain limits as to the maximum cylinder pressure, and, in order to meet government and other shipping regulations, these limits of maximum cylinder pressure must be maintained. So far as the writer knows, there is no reliable pressure indicator on the market which can be used as a maximum-pressure indicator by the average workman in the shop.

Carl A. Jacobson.[9] Is the measurement of pressure at the pre-exhaust point relative rather than absolute? In other words, will this measurement, which is to be used as a means of determining the loading of different cylinders, have to be calibrated for each individual engine? Also, is it necessary to determine at which particular point ahead of the exhaust the orifice should be located?

V. L. Maleev.[10] While not wishing to detract anything from the value of the research work done by the authors, the writer questions its practical value. It so happened that 14 years ago when the writer was employed by the Western Enterprise Engine Company of Los Angeles, we, not because we were lazy but because we were too busy, wanted to find a short cut for determining the horsepower developed by an engine under given operating conditions, when the engine was installed. We wanted to know whether the engine was operating with a normal load, an overload, or if the load could be yet further increased safely. At that time the writer conducted a little research. Five engines were available, ranging from 80 hp to 300 hp, with from three to six cylinders. With these engines a start was made in investigating the relationship between the brake mean effective pressure and the exhaust temperature. The results were incorporated in a paper presented before the Oil and Gas Power Division of this Society in 1927.

At that time the relationship developed between the five engines, which were all of the same type, could be covered very nicely by a curve which was almost a straight line similar to that shown in Fig. 6 of the paper, comparing brake mean effective pressure with exhaust temperatures. Since the authors probably wil continue their work, it would be very interesting if they would at the same time keep a close tabulation of the exhaust temperatures. They may find that this complication of taking pre-exhaust pressures is not necessary, that the temperature curve will be very close to their curves.

K. J. DeJuhasz.[11] A reliable, simple, and accurate instrument for determining the distribution of load among the various cylinders of a multicylinder Diesel engine has been a long-standing engineering problem. Various indicators for maximum pressure, mean indicated pressure, and exhaust temperature have been proposed, tried, and found wanting. The basic objection is that all of these give inferential indications, based upon an assumed indicator diagram. The assumed interrelation is valid only as long as the indicator diagram obeys the assumed law. However as soon as the law of the indicator diagram changes, the simple relationship of these inferential instruments is upset, and the results become misleading.

These objections are fully valid against the method and instrument described by the authors. Incidentally, contrary to the statement of the authors, the broad idea itself is not new. About 20 years ago the writer was associated with a firm of indicator manufacturers in Germany in connection with the development of his phasing-valve indicator. Full consideration was at that time given to the possibility of keeping the phase of the opening of the indicating valve constant at a preselected phase of the engine cycle, and thereby obtaining a continuous indication of the load condition of the engine. A simplified device, using the engine piston itself as a phasing valve, in connection with a check valve, as described in this paper, was fully considered. A modification, using two check valves, one for the maximum and one for the minimum pressure occurring at the preselected travel of the engine piston, and measuring thereby the difference between the maximum and minimum pressures by means of a differential pressure gage, was also investigated and discarded. And probably even then the idea was not new; the German patent DRP 347,840 filed in 1919 by the Liebra Company shows tapped openings in the engine cylinders, bearing a close similarity to the method described by the authors.

Possibly the patent referred to by the authors does not claim the broad idea as such, and the question of novelty, in any case, is unimportant in this discussion. The important question is: Does the proposed method offer advantages in comparison with other differential methods? Let us make comparisons.

1 *Maximum-Pressure Gages.* Assuming a certain type of indicator diagram, a correlation formula can be developed or experimentally determined between the maximum pressure (Otto cycle, or mixed cycle) and the indicated mean pressure, the value of the maximum pressure being in itself of no significance. It can be objected that the maximum pressure puts greater demand on the ruggedness of the check valve; but these demands can be met by suitable design, construction, and materials.

2 *Mean-Pressure Indicators* (averaging the time integral of the cylinder pressures). Such an indicator is described in DRP 416,623 (1923) and DRP 540,803 (1929) issued to Geiger. The inferential relationship with the mean indicated pressure is closer in this case, because all the cylinder pressures have influence on the indication and not only that in one phase.

3 *Exhaust Pyrometer.* If such instruments are suitably designed and carefully mounted to minimize the influence of the other cylinders, and the heat conduction from the manifold walls, then the correlation appears to be about the same as with the pre-exhaust pressure gage. There is the advantage in favor of the pyrometers in that (1) they use wires which are easier to mount and connect, and (2) several thermocouples can be connected by switch to the same voltmeter and, therefore, accidental errors of calibration of the indicating instrument (in the case of pre-exhaust pressure, several pressure gages) cannot occur.

4 *Smoke-Density Meters.* Such meters have been mentioned by the authors. These instruments are intended to measure the completeness of combustion rather than the cylinder load. High smoke density can occur with both high and low load. Therefore, smoke meters are unsuited for gaging engine load and cannot be fairly compared with load-measuring instruments, apart from the fact that smoke meters proposed up till now are not suitable for use on each cylinder of a multicylinder engine.

[8] Fairbanks, Morse & Company, Beloit, Wis.

[9] Fairbanks, Morse & Company, Beloit, Wis. Jun. A.S.M.E.

[10] Research Professor of Mechanical Engineering, Oklahoma A.&M. College, Stillwater, Okla. Mem. A.S.M.E.

[11] Professor of Engineering Research, The Pennsylvania State College, State College Pa. Mem. A.S.M.E.

There are some factors which may influence the correlation of the pre-exhaust pressure with the same indicating pressure; namely, (1) if the uppermost ring is worn, and the next lower ring is not worn, or (2) if the uppermost ring gap happens to be at or near the tapped hole for the pressure-gage connection, then high pre-exhaust pressures will be shown even at low cylinder loads, giving an entirely erroneous indication.

From the foregoing consideration, it appears that the method and apparatus described by the authors is not superior to other existing inferential methods, but on the contrary, is open to serious objections.

These comments are not intended as an adverse criticism, and still less as a discouragement to further efforts. The problem is so important and so difficult that all efforts should be made to develop an ideal instrument which will be really useful to the operating engineer. From the description of the instrument, it is evident that considerable effort and technical skill went into its construction. Some aspects may have eluded the writer's attention which would make even the uncertain data supplied by this instrument of some help to the operating Diesel engineer in certain cases, in preference to no guide at all. However, the conclusion is inescapable that the quest toward a reliable, simple, and accurate instrument, as a substitute for the laborious procedure of indicating, for improving the operation of Diesel engines, is not ended.

Authors' Closure

The leak-by orifice consists of a small drilled hole in which a piece of stainless-steel wire fits snugly, but not tightly enough to prevent the desired outflow of gas. The wire may be moved back and forth by hand to clear the opening, if any deposition of soot should occur. The determination of the leak-by hole size is not very critical; if too small, the response is slow under rapidly varying pressures, and if too large, the pressure reading is somewhat low. When the engine stopped, in a period of about 3 min, the pressure reduced to zero. This was roughly the magnitude of the leak-by used.

Actually, in our experimental work, we were seeking to determine the definite pre-exhaust pressure existing at a given instant in the engine under test, and so the pressure was reduced by the release cock and then allowed to build up until we were certain that the correct value was indicated.

If there is excessive blow-by, the gage will indicate the existing maximum blow-by pressure. An indication would immediately be given that the engine operation was erratic. The high pressure would indicate sticking rings. The gage always indicates the maximum pressure at the measuring point, whether it is a pressure which occurred much earlier in the cylinder or not. However, in an engine under reasonable conditions, i.e., with rings free and worn in, that should not happen at all, and the true pre-exhaust pressure should appear. For example, another case where high pressures may exist is that of a large Diesel engine being started with compressed air. In that case, a small release valve somewhere on the chamber protects the gage.

The first question Mr. Kates asked was why this was better than taking the exhaust temperatures. In some cases perhaps it is not; in many cases it is. We were not especially interested in this method alone when we started the investigation, and tried using exhaust temperatures, which we found did not work well. The engine could be made to balance with exhaust temperatures at certain loads, while at other loads it would be out of balance. When considering scavenging air, the exhaust temperature for a given fuel-pump injection quantity of oil definitely will be affected by variations in quantity of scavenging and supply air. Although a slightly richer mixture would not necessarily affect the pressure, it may affect the temperature. Scavenging conditions in many multicylinder two-stroke-cycle engines are decidedly different among the different cylinders.

We did not experience any trouble from clogging or corrosion. The explanation probably is that in a two-stroke-cycle engine, when the piston gets to a point near the end of the stroke, it is in the cold part of the cylinder where the exhaust gases have cooled down to 800 to 1200 F. At this point, lubrication on the cylinder wall is relatively good. Thus, any oil coming through the pipe is of good quality. Let us assume that a certain amount of oil is coming through, which eventually would collect in the lower part of the chamber. If there is too much, it can be allowed to run out. All of our experience demonstrates the fact that the oil in the chamber is relatively clean. To protect the gage, instead of hooking it in at the high point, it was connected at a low level, thus the oil served to reduce or prevent corrosion of the gage. Sometimes the chamber would be filled with oil at the start of a test and never checked again during the entire series. No apparent trouble from clogging occurred. The fact that the connection is in the lower part of the chamber is a saving feature.

Mr. Kates questioned why a straight line is shown in Fig. 6, and why it is curved in Fig. 7. It can be seen from the plotted points that a curved line might have been produced in Fig. 6, as well as in Fig. 7, although it would not have as much curvature. In general, the tendency has been more toward the type of Fig. 7 than of Fig. 6. In happens that the points as plotted in Fig. 6 produced a "straight-line curve."

Individual readings for the two-cylinder Worthington engine were quite close since the pre-exhaust pressures were adjusted to read the same, the engine being balanced in that condition. It so happened that the indicated horsepower developed by each cylinder came into line. In no instance did it vary 10 per cent and in most cases was in the neighborhood of 3 to 4 per cent.

Prof. Degler's questions are of considerable interest. We did not use snubbers as such, but there was a steel- or glass-wool packing in each line which somewhat served the purpose. Many of the matters which Prof. Degler mentioned are still under investigation.

While we did not do so, the correct size of the chamber could have been determined by theoretical calculation. In the case of the larger low-speed engine, a piece of $2^1/_2$-in. pipe 8 in. long was welded on top and bottom and used for the chamber. In the case of the small high-speed engine, a casting was used as the chamber, the size being about 4 cu in., thus much smaller. Further work is planned for this phase of the study.

In reply to Mr. Jacobson, a pressure calibration should be made for each type of engine. For each type of engine under reasonably similar operating conditions the pressures should be the same. It is safe to say that for a given type of engine there is a certain value of pre-exhaust pressure which can be directly associated with brake mean effective pressure. For the three engines tested, adjustments were made in the pressure readings to allow for differences in the percentages of stroke at which the cylinders were tapped for the gage-pressure lines. The result of these adjustments to a common basis shows a remarkably close correlation in the values of pre-exhaust pressure indicated for each engine, and accounts for the deviations apparent from a casual reading of the curves. For purposes of record it may be mentioned that the engines were tapped in percentages of downstroke as follows: Bethlehem 60.4 per cent, Worthington 67 per cent, and Waukesha 80 per cent.

Replying to Mr. Jacobson's second question, when tests were first undertaken, an attempt was made to approach the actual release point closely; later it was found that it made no difference if we went farther up on the curve.

Prof. Maleev's comments are appreciated. The authors have used temperatures for years as a means of indicating load and

load balance, but with discouraging results. Definitely, the results have shown that the temperatures are not as reliable as this method of pre-exhaust-pressure measurements.

The possibility of measuring pre-exhaust temperatures was also considered. If at the bleeder point where the cylinders are tapped, we also tap the gases and measure the temperatures, we have an index which is fairly reliable, in fact about as reliable as the pre-exhaust pressures. However, a flow condition must be established in order to measure the temperatures, which is one of the difficulties with temperature measurement at that point.

Prof. DeJuhasz develops some interesting points, with many of which the authors are heartily in agreement. However, certain comments are so much at variance with the findings of the paper that some recapitulation seems desirable.

The present discussion does not deal with the measurement of heterogeneous pressures at any point in the engine stroke but with the specific measurement of pressure in the region just before exhaust where the pressure gradient per unit of piston travel has essentially reached its minimum value. In this region the often extreme fluctuations of the combustion process have been essentially smoothed out, and the pressure variations observed are less abrupt and apparently give an average more rational index of conditions than can be found in terms of pressure at any other point in the stroke. Whether or not the idea is new and whatever the status of the patent situation may be, are matters of no concern to the authors. However, in so far as could be ascertained, several years ago, when this project was first started, the only reference to the use of the pre-exhaust range for load indication was the one indicated in the paper, and no formal work was found in the literature. Since specific reference has been made to the German patent DRP 347,840, filed in 1919 by the "Liebra" Motorengesellschaft, it should be mentioned that the authors were familiar with this patent but completely failed to find therein any claims that the pressure obtained from any one single point of piston travel would indicate a relationship to the amount of power developed. On the other hand, the substance of the "Liebra" patent seems to apply wholly to an engine construction designed for the purpose of obtaining an indicator card by the "point-by-point" method, similar to that using a phase-changing indicator. Further, in the "Liebra" arrangement, the piston does not uncover the ports itself, as the timed uncovering is accomplished by a sleeve member interposed between the piston and the cylinder.

Maximum-pressure gages are indeed useful instruments, and correlation formulas for the indicated mean effective pressure in terms of the theoretical maximum pressure can be derived for some oil-engine cycles. However, for the actual engine cycle, how much confidence can be placed in the reading of maximum pressure as either an index of the load or load variation? In the authors' opinion and in the opinion of most of the Diesel operators with whom this question has been discussed, there can be none. The variations of the combustion process and slight changes in injection timing can appreciably change the maximum pressure, often with little change in mean effective pressure. In the case of a theoretical Diesel cycle, moreover, the load could change from zero to 100 per cent without any change in maximum pressure being indicated. Consequently, it is not surprising that the gage, reading the difference between maximum and minimum exhaust pressures, mentioned by Prof. DeJuhasz, was investigated and discarded.

A mean-pressure indicator, averaging the time integral of cylinder pressures, as a device for indicating developed load in an engine, represents what might be called an ideal. But it is an ideal not easy to attain, as such instruments are expensive and involve so many complications in installation and use that supplying and servicing a multicylinder engine with a set of such units practically falls back as the job for a laboratory technician and not that of an operating engineer.

The authors have no intention of minimizing the importance of the exhaust-temperature indicator as a device for indicating load balance among the cylinders of a Diesel engine. In many cases, this device performs meritorious and fine service. However, like anything else, it has its limitations and some of these are indicated in the paper. Scavenging-air variations with two-cycle engines, radiation, and conduction to or from the couple, can all affect the reading independently of load variations. In regard to ease of attachment, it is but slightly more difficult or expensive to run $^1/_4$-in. tubing than to run electric cable for the pyrometers. The cables themselves require careful soldering and adequate insulation against grounding. It is quite possible also to use a pressure-selector valve and one gage for a multicylinder engine, but the instantaneous picture of engine balance or nonbalance offered by a group of gages, indicating pre-exhuast pressures, eliminates the necessity of remembering all the other values as a selector is turned from point to point. The relatively low cost of gages makes the instantaneous picture feasible.

Professor DeJuhasz's comment as to the influence of the condition of the uppermost piston ring upon accuracy of the readings is well taken. Under such conditions, the pressure indication is sufficiently greater than normal to show that the piston ring is worn, stuck, or otherwise in need of attention or replacement. It is this very characteristic, in serving to indicate piston-ring performance, that makes the pre-exhaust-pressure method valuable to the engine operator.

The authors realize that this device is not the answer to all the Diesel operators' worries but feel the experimental data obtained have shown that the method is so reliable and useful as a load-indicating device that the research has been well worth while.

Design of Diesel-Engine Foundations

By KENNETH H. LARKIN,[1] KANSAS CITY, MO.

In this paper the author discusses all of the factors encountered in the layout, design, and construction of foundations for stationary Diesel engines of the vertical type. The factor requiring the greatest attention and consideration of designers is that of reducing or isolating the vibration of the engine. This matter is treated comprehensively. The author applies accepted theories and engineering principles to the problems. As in most engineering problems, the exercise of sound judgment enters to a large extent. The paper is presented in outline form, the subject matter following the sequence generally encountered in an actual design.

A PROPERLY designed engine foundation serves two purposes (1) it furnishes a place to set the engine, and (2) it acts to reduce and isolate the vibration of the engine due to the dynamic unbalance of its moving parts. The factors to be considered in fulfilling the first purpose of an engine foundation are technically simple, and satisfactory details have been fairly well standardized. The factors to be considered in fulfilling the second purpose are many and technically difficult because there are so many elements which cannot be treated analytically. However, by considering these factors in the light of accepted theories and engineering principles, with the exercise of sound engineering judgment, a satisfactory design may be assured. We sometimes hear of troublesome foundations but an inspection of each reveals a violation of some fundamental principle.

An engine foundation is a poor place to economize. Yet this is often done because of the failure of those handling the finances to realize the important part that an adequate foundation plays in the operation of the entire plant. The saving of a few hundred dollars in the cost of a foundation is little short of ridiculous if such saving jeopardizes the operation of the engine and risks the expenditure of several thousand dollars to rebuild the foundation adequately.

Consideration of Site of Operation

The first factor to be considered in the design of an engine foundation is the site of its operation. This includes the general features of the neighborhood (proximity, construction, and use of surrounding structures, possibility of interference with other operations in the same building, etc.) and characteristics of the subsoil on which the foundation will rest. If the engine is to be installed in a residential neighborhood, or within a hotel or apartment house, the foundation must be very efficient in isolating the engine vibration. If the installation is well removed from other structures or located in a manufacturing district, less attention need be given to this factor. At any location where the engine vibrations are likely to interfere with the activities or rights of others, this should be given thorough attention, because such interference may result in legal action prohibiting the operation of the engine. When the engines are operated in competition with electric utility companies, this factor must be given considerable attention because excessive engine vibration is a favorite basis for enjoining the operation of the competing equipment.

Subsoil. Some definite knowledge of the foundation soil is necessary. An auger boring extending at least 15 ft below the bottom of the foundation is generally adequate. A log of the boring should be made and samples of soil, taken at say 3-ft intervals, should be carefully inspected for general composition, moisture content, stability, etc. In granular soils it is important to take undisturbed samples and determine the percentage of voids by laboratory methods. Particular attention should be paid to the existence of ground water, noting the rise of water in the open hole. There is no point in making soil-loading tests, except possibly deflection tests as noted subsequently, because the static load of the engine and foundation can always be kept below 2000 lb per sq ft, and hence can be carried by practically any soil as far as its capacity for static load is concerned.

It is often desirable to know the natural vibration frequency of the elastic system, consisting of the engine, its foundation, and the subsoil, because the amplitude of the vibration is greatly increased if this natural frequency is very close to the forced frequency of the engine. The proof of this statement and an explanation of how this natural frequency can be determined is given in the following paragraphs.

It is pertinent to define some of the commonly used terminology of vibration engineering.

"Vibration" is a periodic motion which changes direction twice during a complete cycle and repeats itself after a certain interval of time.

"Period" is this interval of time (measured in seconds).

"Simple harmonic motion" is the simplest type of periodic motion. When the displacement is plotted against time, a pure sine curve is obtained.

"Cycle" is a complete movement of a vibrating body, measured from the time it passes through the equilibrium point until it again passes through this point, traveling in the same direction.

"Frequency" is the number of cycles of motion per unit time (measured in cycles per second f, or radians per second p, where $p = 2\pi f$).

"Amplitude" (A) is the magnitude of the vibratory motion measured from the equilibrium point to the extreme position (measured in inches).

"Natural frequency" (f in cycles per sec or p in radians per sec) is that frequency at which an elastic system will vibrate after having been displaced from the equilibrium position and then released.

"Forced frequency" (ω in radians per sec) is that frequency at which an elastic system will vibrate when acted upon by a periodic force of any frequency.

"Resonance" is that condition when the natural frequency is the same as the frequency of the periodic force.

"Damping" is the reduction of the amplitude of vibration due to natural forces as air, or liquid resistance, imperfect elasticity, etc., or artificial forces as dashpots, etc.

The theory of vibrations[2,3] shows that for the case of forced vibration with viscous damping

[3] "Vibration Problems in Engineering," by S. Timoshenko, D. Van Nostrand Company, Inc., New York, N. Y., 1937, pp. 38–51.

$$A/\Delta = \frac{1}{\sqrt{(1 - \omega^2/p^2)^2 + (2C \cdot \omega/p)^2}} \quad \ldots\ldots\ldots [1]$$

where A = amplitude of forced vibration
Δ = deflection due to static load of same magnitude as unbalanced periodic force of engine
ω = frequency of unbalanced periodic force of engine
p = undamped natural frequency of elastic system
C = coefficient of damping; $C = 1$ is point of critical damping where damping is so great as to prevent vibration

The right-hand term in Equation [1] is often called the "magnification factor." If we draw curves for various values of C, we see that the curves in Fig. 1 all have a sharp peak near

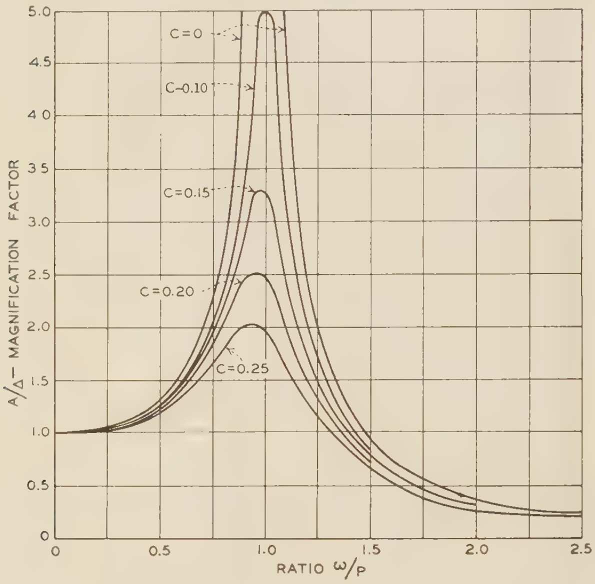

FIG. 1 CURVES OF COEFFICIENT OF DAMPING

$\omega/p = 1$ for all values of C. Note that when $C = 0$ the value of A/Δ approaches infinity for ω/p ratios near 1 and that for the larger values of C the peak of the curve corresponds to a ω/p ratio slightly less than 1, departing further from $\omega/p = 1$ as the values of C increase. Note, furthermore, that the curves are not greatly different for ω/p ratios outside the range 0.5 to 1.5.

This theoretical relation is approximately true for an engine foundation on an elastic subsoil. Its value lies not in determining the numerical value of the amplitude of vibration but in proving, as stated, "the amplitude of vibration is greatly increased if this natural frequency is very close to the forced frequency of the unbalanced forces of the engine" and in showing how such a condition can be avoided. The value of C will vary for different soils but, if we assume $C = 0.25$ as an average, we can see that if we avoid ω/p ratios between 0.5 and 1.25 the amplitude of vibration will not be greatly increased.

The theory of vibration[4] further shows that, for an elastic material conforming to Hooke's law

$$p = \sqrt{\frac{g}{\Delta}} \text{ or } f = 188\sqrt{\frac{1}{\Delta}} \text{ cycles per min} \ldots\ldots\ldots [2]$$

where

g = acceleration of gravity
Δ = static deflection of elastic material

[4] Reference 2, p. 44.

This relationship is shown graphically in Fig. 2, and is approximately true for most soils. Thus, if we know the value of Δ we can predict the undamped natural frequency from Fig. 2, and the magnification factor from Fig. 1. The value of Δ should be determined in the field by static-load tests on the soil stratum at the bottom of the foundation. The static soil load, due to the engine and foundation, will be low, usually between 1000 to 2000 lb per sq ft and, by taking several readings within this range, the value of Δ for the actual load can be later interpolated. The undamped natural frequency for some typical soils is given in Table 1.

TABLE 1 UNDAMPED NATURAL FREQUENCY FOR TYPICAL SOILS

Material	Loading, lb per sq ft	Undamped natural frequency, cycles per min
Clay (wet)	2000	540
Clay (wet)	4000	380
Clay (dry, hard)	2000	660
Clay (dry, hard)	8000	330
Gravel	2000	1330
Gravel	8000	660
Sandstone	2000	4200
Sandstone	8000	2100

The author feels that the general features of the site as affecting the allowable vibration and the character of the subsoil to respond and transmit vibration should always be considered in the pur-

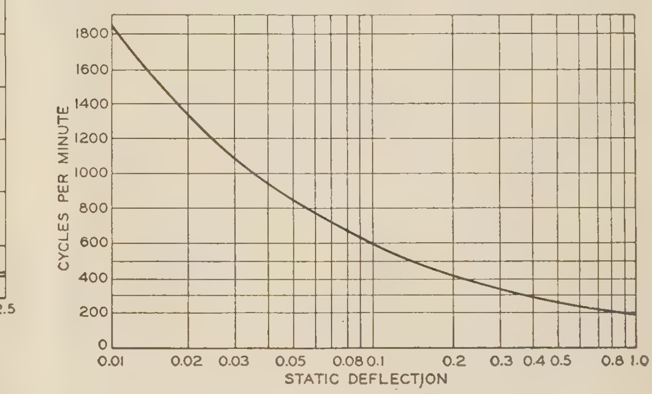

FIG. 2 UNDAMPED NATURAL FREQUENCY

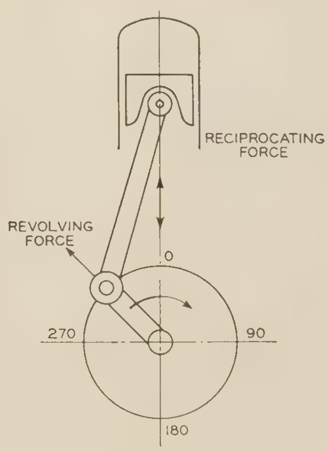

FIG. 3 ENGINE MECHANISM

chase of the engine. Of course, a foundation can be designed for any engine at any site, but if conditions are such that vibration of adjacent structures is undesirable, or if the subsoil is of a type to respond to and transmit the engine vibrations, then the pur-

chase of an unbalanced engine is poor judgment, because all the methods of foundation design and vibration isolation can never be a proper substitute for engine balance.

Cause of Vibration—Unbalanced Engines

Source of Unbalance. It is pertinent to consider the cause of unbalance in engines and the source of the forces which cause vibration of the engine and foundation. These forces are all inertia forces due to the change in motion of the moving parts of the engine, and are often called "free inertia forces" because they are not self-contained within the engine frame but are resisted only by the mass of the engine and foundation. The gas pressure in the cylinders causes no unbalanced forces outside the engine frame.

If we consider the forces acting in a one-cylinder vertical engine, Fig. 3, we observe that the mass of the crankshaft throw and pin revolves at uniform speed, causing a centrifugal inertia force, which has vertical and horizontal components varying in simple harmonic manner with a frequency equal to the engine speed. The mass of the piston reciprocates in a vertical line, reversing direction twice each cycle, causing vertical inertia forces. Because of the angularity of the connecting rod, the motion of the piston and, hence, the inertia force, is not of simple harmonic character, Fig. 4, but may be resolved[5] into two forces which vary in simple harmonic manner; one termed "primary force," having a frequency the same as the engine speed, and the other termed "secondary force," having a frequency twice the engine speed.

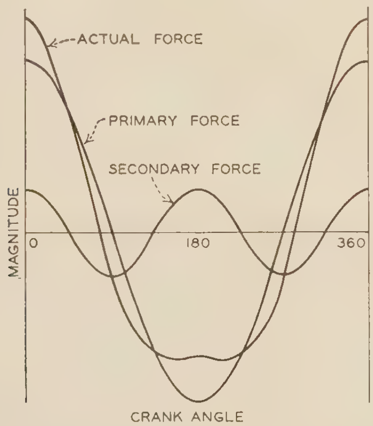

Fig. 4 Inertia Force of Reciprocating Mass

The connecting rod has a complex motion intermediate between that of the crankpin and the piston; the motion of the lower part resembling that of the crankpin and the motion of the upper part resembling that of the piston. However, the treatment of the connecting rod can be greatly simplified if we consider the mass of the rod distributed into two portions, one concentrated at the piston pin and one concentrated at the crankpin, such that the center of mass of the two portions coincides with the center of mass of the actual connecting rod. This involves no error whatever and, since the first mass has the same motion as the piston and the second mass has the same motion as the crankpin, we have not added any new forces but merely increased the inertia forces already considered by increasing the mass of the moving parts.

Summarizing, we have three inertia forces all varying in a simple harmonic manner, one a revolving force with horizontal and vertical components varying with a frequency the same as the engine speed, one a vertical force (primary) with frequency the same as the engine speed, and finally a vertical force (secondary) with a frequency twice the engine speed. The vertical component of the revolving force is in phase with the primary force at all positions. Hence, they can be added and considered as one force (the primary force as sometimes defined includes both these forces). The secondary force is in phase with the primary force only when the crank is at upper dead center.

Means of Balancing. Having determined the unbalanced forces normally existing in a one-cylinder engine, we are next interested in eliminating them or balancing the engine. The revolving force can be completely eliminated by counterweighting the crankshaft with an equal mass moment placed opposite the crank throw. This procedure is followed by most manufacturers. By further increasing the counterweight, we can reduce the primary vertical force or even make it zero. However, this additional counterweight (beyond that required to counterbalance the revolving force) introduces a horizontal unbalanced force. This horizontal unbalance is equal to the amount of reduction of the primary unbalance, the effect being that of turning part of the primary unbalanced force at 90 deg to its original direction. Because unbalanced horizontal forces are usually more serious than unbalanced vertical forces, there is not much to be accomplished in this manner. It is the practice of engine manufacturers to counterbalance not more than $^1/_3$ to $^1/_2$ of the primary vertical force.

Little can be done toward balancing the secondary force. The Lancaster balancer, a mechanism of two weights driven from the crankshaft at twice crankshaft speed, with weights revolving in opposite directions and so arranged that the vertical forces balance the secondary force and the horizontal forces balance each other, is 100 per cent effective. However, it is an expensive device and its use is seldom economical.

Multicylinder Engines. When we enter the field of multicylinder engines, we must consider the resultant at any instant of the unbalanced forces for each cylinder. In so doing, we find that by certain crank arrangements, the unbalanced forces of individual cylinders can be made to balance each other. We find, furthermore, that because the forces of the individual cylinders are not in the same transverse plane they sometimes cause unbalanced moments about a vertical or transverse axis even when the resultant of the forces for the entire engine is zero.

We have seen that the mass of the crank throw, pin, and lower part of the connecting rod produces a force revolving at engine speed. It can be shown[6] that the primary force can be represented as the vertical component of a vector revolving at engine speed and the secondary force as the vertical component of another vector revolving at twice engine speed. In the light of this, it is easy to study balance conditions of multicylinder engines by means of rotating vectors, the vectors being spaced apart by the same angles as the crank throws.

Consider a three-cylinder engine with cranks 120 deg apart. With No. 2 cylinder at upper dead center, No. 1 and No. 3 cylinders are in the positions shown in Fig. 5, and the revolving forces are balanced as shown in Fig. 6(*a*), except that the horizontal components of the forces 1 and 3 form an unbalanced rotating couple. This couple can be balanced by two weights *A* and *B* placed on the end crank throws, and counterweights on No. 2 crank throws are unnecessary.

Considering the primary forces, that of No. 2 cylinder is a maximum and will be represented as a vector directed upward, Fig. 7, the vector representing No. 3 cylinder had this location 120 deg of rotation previously and that of No. 1 cylinder will have

[5] Reference 2, p. 209.

[6] Reference 2, p. 215.

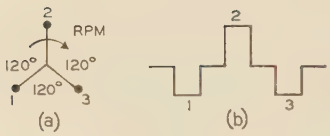

Fig. 5 Crank Arrangement

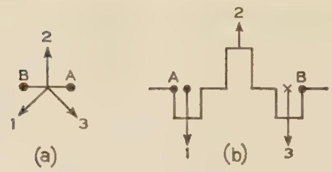

Fig. 6 Revolving Force

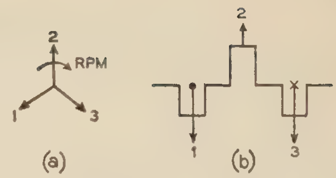

Fig. 7 Vectors of Forces

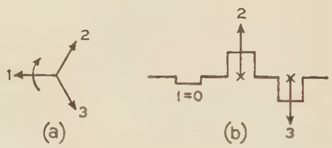

Fig. 8 Primary Forces

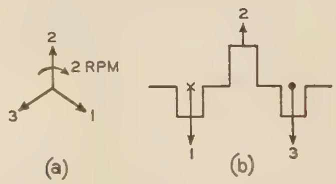

Fig. 9 Secondary Forces

this location 120 deg of rotation hence. Therefore, the revolving vectors representing these forces are as shown in Fig. 7, and are similar to the revolving forces of Fig. 6(*a*).

Because the primary forces being studied, Fig. 7, are the vertical components of these revolving vectors, it is obvious that the forces are balanced for all crank positions. However, there is an unbalanced moment, varying in simple harmonic manner with frequency equal to engine speed, due to the fact that forces 1 and 3 are not in the same plane as force 2 and the resultant of their moments about the center of No. 2 cylinder varies as the vectors revolve. This moment is passing through zero value for the crank position shown in Fig. 7(*a*), but consider its value as vectors revolve to crank position shown in Fig. 8. This moment is called the primary moment.

Considering the secondary forces, that of No. 2 cylinder is a maximum and will be represented as a vector directed upward. Then, since the secondary-force vectors are revolving at twice engine speed, they will have positions shown in Fig. 9. By reasoning similar to that for the primary forces, we see that the secondary forces are balanced for all crank positions, but that again there is an unbalanced moment varying in simple harmonic manner, only now with a frequency equal to twice engine speed. This is called the secondary moment.

TABLE 2 ENGINE BALANCE

No. of cylinders	Crank sequence	Forces		Moments	
		Primary	Secondary	Primary	Secondary
3 (2 ~ or 4 ~)	120° Cranks 1–3–2	Balanced	Balanced	Unbalanced	Unbalanced
4 (2 ~)	90° Cranks 1–3–4–2	Balanced	Balanced	Unbalanced	Balanced
4 (4 ~)	180° Cranks 1–4, 2–3	Balanced	Full unbalance	Balanced	Balanced
5 (2 ~ or 4 ~)	72° Cranks 1–5–2–3–4	Balanced	Balanced	Small unbalance	Unbalanced
6 (2 ~)	60° Cranks 1–6–2–4–3–5	Balanced	Balanced	Balanced	Small unbalance
6 (4 ~)	120° Cranks 1–6, 3–4, 2–5	Balanced	Balanced	Balanced	Balanced
7 (2 ~ or 4 ~)	51°–26′ Cranks 1–6–5–3–2–7–4	Balanced	Balanced	Balanced	Unbalanced
8 (2 ~)	45° Cranks 1–8–6–2–4–5–7–3	Balanced	Balanced	Balanced	Balanced[a]
8 (2 ~ or 4 ~)	90° Cranks 1–8, 4–5, 2–7, 3–6	Balanced	Balanced	Balanced	Balanced

[a] Space between Nos. 4 and 5 cylinders increased to 1.828 regular spacing.

In this manner the balance conditions of any multicylinder inline engine can be investigated. The balance for some of the common crank arrangements for engines from three to eight cylinders is given in Table 2.

Mode, Frequency, and Magnitude of Vibration. It should be noted that unbalanced forces cause the engine to stamp up and down on its foundations, while unbalanced moments cause it to pitch fore and aft. Also, that the frequency of primary forces and moments is equal to engine speed, while that of the secondary forces and moments is equal to twice engine speed. The magnitudes of the primary and secondary forces are in the same ratio as

$$\frac{\text{Length of connecting rod}}{\text{Radius of crank}} \text{ (approximately 4 for average engine)}$$

In practice no perfectly balanced engines are constructed because the dissimilarity of parts for the different cylinders will cause some unbalanced forces and moments, both primary and secondary. Because the inertia forces due to unbalanced parts vary directly as the square of the speed, the higher the engine speed the greater attention is required to the engine balance.

Design of Foundation

Manufacturer's Drawings. Having purchased the engine, the layout of the foundation can begin. The manufacturer will provide a "certified" foundation drawing. Do not be misled, "certified" merely means that the holes for the anchor bolts and general shape of the engine base will be as shown; the engine manufacturer will assume no responsibility for the design of a successful foundation, and it is not to be expected that he should. However, these drawings usually show over-all dimensions and give a recommended yardage of concrete for the foundation.

Foundation Yardage. A tabulation of the foundation yardage recommended by engine manufacturers gives the average values shown in Table 3. All of the foundations tabulated fell within 20 per cent of these average values and the large majority were within 10 per cent.

The data were taken from manufacturers' catalogues and bid strips, and cover many speeds and cylinder sizes. The engines were both 2-cycle and 4-cycle, the majority with speeds ranging from 225 to 327 rpm; most of the 2-cycle engines developing

TABLE 3 AVERAGE VALUES OF FOUNDATION YARDAGE

No. of cylinders	3	4	5	6	7	8
Foundation cubic yards per engine horsepower	0.141	0.120	0.108	0.100	0.096	0.091
No. of engines tabulated	7	10	20	20	14	14

from 75 to 360 hp per cylinder and the majority of 4-cycle engines developing from 75 to 130 hp per cylinder. The extreme limits of the tabulated engines were a 2-cycle engine running at 150 rpm developing 680 hp per cylinder available in 5, 6, 7, and 8 cylinders; a 4-cycle engine running at 400 rpm developing 83 hp per cylinder available in 5, 6, 7, and 8 cylinders; and a 4-cycle engine running at 327 rpm developing 55 hp per cylinder available in 3 and 4 cylinders.

The tabulation reveals no relation of foundation yardage either to engine speed or cylinder size; all of the extremes mentioned are within 10 per cent of the average values shown in Table 3.

This yardage of concrete is the result of experience with damping the engine vibration. Manufacturers generally state that it is based on a hard firm subsoil. Theoretically, the anchorage of an engine to a large mass of concrete is an application of the theory of mass damping which is based on the principle of using the small accelerations set up in a large mass to balance the large accelerations of a small mass (unbalanced engine parts). This may be expressed

$$P = Ma = M\omega^2 A \qquad [3]$$

or

$$A = \frac{P}{M\omega^2} \qquad [4]$$

where P = unbalanced periodic inertia force of engine
M = mass subject to vibration (engine, foundation block, and a part of subsoil)
a = acceleration
ω = frequency of periodic force
A = amplitude of vibration of foundation block

This relation, Equation [3], assumes the natural frequency of the foundation is infinitely large and that the magnification factor, Fig. 1, is unity. This is approximately true for ω/P ratios less than 0.5.

By means of this relation, we might determine the mass of the foundation block which would be required to limit the amplitude of vibration to any predetermined value, if we knew just how much of the subsoil should be included in the mass subject to vibration. However, this is so variable—depending upon the type of subsoil, unit loading, whether the foundation sets in or on the subsoil, and probably other factors—that the theory of mass damping cannot be accurately applied and, as stated, the mass of the foundation block is generally determined by experience.

Notwithstanding, this theory can be qualitatively applied, indicating that the amplitude of vibration will vary directly as the unbalanced inertia force and inversely as the mass subject to vibration. Therefore, it is clear that any means for increasing the mass of earth subject to vibration will reduce the amplitude of vibration. We might accomplish this by tamping the earth solidly around the foundation block, driving long piles into the subsoil, etc. In general, there is not much to be gained by increasing the size of the foundation block beyond the values shown in Table 3.

Miscellaneous Details. Having the certified drawing, the location of anchor bolts can be made, pits for the flywheel, generator, etc. can be provided, as well as openings for pipes, conduits, drains, etc.; in short, the entire upper part of the foundation can be laid out. The author recommends Fig. 10 as a standard anchor-bolt detail. It is economical, provides for inaccuracy of setting, and allows the withdrawal of the bolt during setting of the engine bed plates or in case of a broken bolt. The use of long anchor bolts is recommended as they stretch more under a given load, allowing a degree of resiliency and are not so apt to break because the unit stress is thereby lowered. Any pits in the foundation should be provided with a drain extending through the foundation.

The pit for the flywheel, generator, or other driven machine should be surrounded by a protecting handrail. A double pipe handrail of welded construction with top rail 30 to 36 in. above floor level is satisfactory as it is rugged, economical, and generally considered of adequate appearance. Safety laws of many states require that such pits be surrounded by curbs or steel kick plates. This feature is never costly and is always recommended.

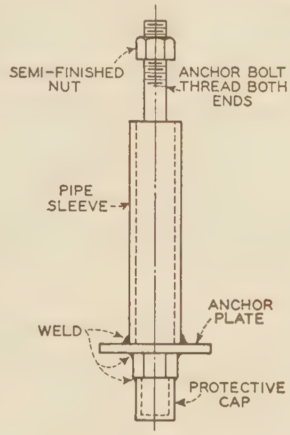

Fig. 10 Anchor Bolts

The inclusion of pipes within the engine foundation is never desirable. Ample openings and chases should be provided for the necessary small piping at the engine end of the foundation and this piping should never be grouted in. Some makes of engines require that the intake-air pipe be encased in the foundation. When this is done the pipe should be wrapped with several layers of tarred felt or asbestos paper; this to allow movement of the pipe under temperature changes without stressing the concrete. The large area of concrete left void by this air piping should be replaced by an equivalent area of reinforcing steel, in order to avoid shrinkage cracks in the foundation. The inclusion of exhaust piping within the engine foundation is an open invitation to trouble unless extensive precautions are taken, as this piping is subject to large expansion due to temperature changes.

Consideration of Subsoil. There remains the design of the lower part of the foundation, the connection to the subsoil. The foundation should always rest on undisturbed soil at a level not higher than the foundations of the power-plant building. The depth of foundation should be not less than 4 to 5 times the stroke of the engine, with a minimum of 5 ft. The width of base should be at least equal to the vertical height from the bottom of the foundation to the center of the shaft and should be increased for engines having unbalanced horizontal forces. This can usually be done at little extra cost by using projecting cantilever footing slabs. The length of base is generally so large that no consideration is required in this direction, except that the length should be so adjusted that the center of gravity of the total weight on the subsoil (foundation, engine, flywheel, generator, etc.) coincides with the center of gravity of the area of contact with subsoil. All the rules cited are strictly empirical and, whenever necessary, should give way to more important considerations.

Where the foundation is to be set on rock, the considerations are few and simple. Practically any type of engine can be operated with a minimum of vibration. The foundation should be well keyed into the rock and often can be reduced in yardage below the limits recommended by the engine manufacturers, other factors permitting. Only in the case of engines installed

inside hotels or apartments is any kind of vibration insulation required with rock foundations. Processed cork slabs are recommended in this case, as the low-frequency vibrations will be absorbed by the rock; it is the higher-frequency vibrations approaching the sound range which have to be isolated.

Where the subsoil is soft, spongy, and water-bearing, the problem is complicated by many factors. First a well-balanced engine should be chosen. A definite attempt should be made to avoid synchronism between the forced frequency of any accidental unbalance of the engine and the natural frequency of the foundation and subsoil. Some compaction of the subsoil should be accomplished by driving piles or subsoil drainage. These efforts, including a conservatively designed foundation block, will usually reduce the vibrations to limits which are allowable in a power plant located at a reasonable distance from habitable structures. A further reduction of vibration will require the use of some vibration isolation, preferably springs.

Other conditions of the site, intermediate between the extreme conditions mentioned, may be satisfactorily solved by the use of intermediate measures. All of these combinations cannot be discussed here but remedies for some of the more critical conditions will be given.

Within limits, the "undamped natural frequency" of the engine, foundation, and subsoil is under the control of the foundation designer. Table 1 indicates that this frequency increases with decreased unit loading. Then, if larger footing areas are used, the natural frequency will be increased and vice versa. It is also evident that both drainage and compaction of the subsoil tend to increase the natural frequency. The removal of subsurface water is always desirable but generally expensive. The driving of closely spaced piles is probably the most effective method of compacting soft subsoils as far as engine foundations are concerned. Other advantages of the use of piling are given herein.

A study of Table 1 indicates that for the problem at hand the forced frequencies are so low that ω/p ratios will never be more than 1.5 and, because we must consider the frequency of both primary and secondary forces, the best procedure is to provide ω/p ratios of less than 0.5, Fig. 1. Considering the secondary forces of a 300-rpm engine, this would require a value of

$$p = 300 \times 2 \times 2 = 1200 \text{ cycles per min}$$

It should be noted that, because of the greater magnitude of primary forces and moments, it is more desirable to avoid resonance with them than with the secondary forces and moments. This is another reason for working on the left-hand side of the peak of the curves of Fig. 1.

Furthermore, it should be noted for firm dense soils the value of Δ will be very low, and the amplitude of vibration will not be very great regardless of the ω/p ratio. Hence, it is only in soft soils that this consideration of the undamped natural frequency becomes important.

At locations where a poorly consolidated granular subsoil is encountered, there is a definite possibility that the vibrations of the engine foundation may cause a rearrangement of the particles and a gradual consolidation. The resulting settlement may be considerable. Such conditions require a careful study of the natural density and effect of vibration thereon. In such locations, the use of piling is generally indicated. The piling will spread the vertical load to lower strata, and the vibration of driving will effect some consolidation. The use of vibration isolation might be considered, if other factors make the reduction of vibration desirable or necessary.

Vibration Isolation

In considering the use of vibration isolation, the first step is to understand the basic theory and then to determine the results which attend the use of various isolating materials.

Theory of Undamped Vibrations

Steel Springs. If we take the case of a weight W supported by a compression spring, Fig. 11, and consider only vibratory motion in the direction of the axis of the spring (an undamped linear system in vibration terminology), it can be shown[7] mathematically that

$$\text{Natural frequency } f = \frac{1}{2\pi}\sqrt{\frac{g}{\Delta}} \qquad [5a]$$

$$p = \sqrt{\frac{g}{\Delta}} \qquad [5b]$$

where Δ = statical deflection of spring due to W, in.
g = acceleration of gravity (32.2 fps per sec)

If the elastic system of Fig. 11, initially at rest, is acted upon by a periodic force $P \sin \omega t$, it can be shown[2,3] mathematically

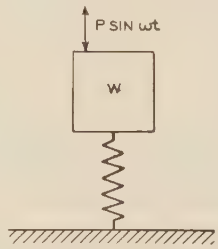

Fig. 11 Weight Supported by Compression Spring

that there is produced both forced vibrations of period ω and free vibrations of period p. In all practical systems, this latter vibration will be eliminated soon after starting due to various damping forces and only forced vibration, having the same frequency as the periodic force, will remain. For this condition it can be shown[2,3] that

$$A = \frac{P\Delta}{W}\left(\frac{1}{1 - \omega^2/p^2}\right) \qquad [6]$$

If we draw a curve for the expression in the parentheses, Equation [6], plotting its value for various ω/p ratios (curve C = 0, Fig. 1), we see that it is always greater than 1 for ratios of ω/p between 0 and 1.41, but that for ratios of ω/p greater than 3, this factor is considerably reduced. Furthermore, at ratios of ω/p approaching 1, the value is very great becoming infinite for $\omega = p$.

Also we see (note Equation [5*b*]) that, with other factors remaining constant, the value of p and hence the amplitude of vibration A is reduced when Δ is increased. We note that this can be done by using a softer spring or heavier weight W or both. Furthermore, the amplitude of vibration is the deflection of the spring under the forced vibration, and the deflection of the spring multiplied by the spring constant gives the force transmitted to the foundation. The spring constant $K = W/\Delta$. Applying this value to Equation [6], we have

$$\text{Force on foundation } F = P\left(\frac{1}{1 - \omega^2/p^2}\right) \qquad [7]$$

and the curve C = 0 of Fig. 1 gives directly the "magnification factor" to be used for various values of ω/p.

Use of Steel Springs. Interpreting this for our particular prob-

[7] Reference 2, p. 44.

lem, we see that, by putting suitable springs under a Diesel-engine foundation, we can reduce the amplitude of the vibrations transmitted to the subsoil and that, by a suitable combination of concrete engine block and supporting springs, we can keep the amplitude of engine vibration within allowable limits. Practically all engines of the type being considered will operate at a fairly constant speed and, by designing for a ω/p ratio of 3 or more, we can greatly reduce the amplitude of transmitted vibration.

However, the elastic system under consideration is of the simplest type and the practical case of vibration damping using springs is complicated by many factors not herein considered. For example, Diesel engines may have unbalanced forces acting in a lateral direction due to unbalanced revolving forces, torques acting to rock the engine in a transverse direction, and couples acting to rock the engine longitudinally. All of these act together on the springs and, under such conditions, the system may have six different modes of vibration each with its own frequency. The complete design of a system of springs for isolating a Diesel engine is quite beyond the scope of this paper, indeed beyond the ability of the average consulting engineer, and should be left to the vibration specialist.

Theory—Damped Vibrations

Cork, Hair Felt, Etc. The analysis as given neglects the effect of any damping forces. This is practically correct for steel springs, the damping effect of which is very small, but is not applicable for other resilient materials. Let us consider the case where cork, sponge rubber, hair felt, or similar resilient material is used for isolating a vibrating mass.

If we assume a material such that the damping is proportional to the velocity ("viscous damping" in vibration terminology), it can be shown [2,3] that

$$A = \frac{P\Delta}{W} \frac{1}{\sqrt{(1 - \omega^2/p^2) + (2C\cdot\omega/p)^2}} \quad \text{........[8]}$$

where C = coefficient of damping, as in Equation [1].

Also

$$F = P \frac{1}{\sqrt{(1 - \omega^2/p^2)^2 + (2C\cdot\omega/p)^2}} \quad \text{.........[9]}$$

The curves for various values of C, shown in Fig. 1, indicate that the effect of damping is to reduce the peak amplitude and force transmitted at the point of resonance. This effect may be of practical importance in reducing the amplitude and transmitted force while the engine is passing through the critical speed.

Use of Cork, Etc. That isolating materials such as cork, hair felt, rubber, etc. conform closely to the relation, Equation [8], has been demonstrated by tests.[8] Thus, if we know the characteristics of these materials we can predict their efficiency as vibration isolators. Of these materials only cork has found much use as an isolating medium under Diesel-engine foundations.

TABLE 4 VIBRATION CHARACTERISTICS OF CORK

Material	Natural frequency, cycles per min	Loading, lb per sq ft	Source of data
Cork, 6 in. thick	420	14400	Anderson[9]
Cork, 1 in. thick	1080	14400	Anderson[9]
Cork, 5 in. thick	600	4000	Jackson[10]
Coarse-ground compressed cork, 2 in. thick	770	4130	Hull[8]
Natural cork, 1.35 in. thick	1450	4460	Hull[8]

The cork producers are either unwilling or unable to furnish any pertinent data on their product. However, certain data, given in Table 4, are available from independent sources.

Values of the damping coefficient $C = 0.11$ and 0.14 for compressed and natural cork, respectively, have been determined experimentally.[8]

Engines of the type under consideration are called medium-speed, say 200 to 400 rpm. Then, the frequency of the primary forces is 200 to 400 cycles per min and that of the secondary forces is 400 to 800 cycles per min. Then for a 400-rpm engine (the upper speed limit considered), the natural frequency of the isolating material must be less than $400/1.414 = 283$ cycles per min to effect any reduction of the vibration due to the primary force and less than $800/1.414 = 566$ cycles per min to effect any reduction of the vibration due to the secondary force. For slower-speed engines those limits would be proportionately lower.

Considering the data of Table 4, and the curve of Fig. 1, it is evident that, even if the natural frequency of cork can be brought to say 400 cycles per min by the use of a considerable thickness and heavy loading, the reduction of secondary forces is not very great and the primary forces may be actually increased. Thus, we see that this material, which has proved very effective in insulating sound and high-frequency mechanical vibrations, is not suited to the isolation of low-frequency mechanical vibrations, because its natural frequency is too high.

Effect of Subsoil. All the preceding theory of isolation considers that the subfoundation under the springs or isolating material is of unyielding character. If the subfoundation is of yielding character, both the amplitude of the forced vibration and the transmitted vibration are increased. There are too many variables to deal with this analytically and it is best handled by keeping the natural frequency of the subsoil as high as possible. Methods of improving the subsoil have already been discussed.

Use of Sand or Gravel Bed. There is one kind of vibration isolation which has not yet been considered. This is a layer of sand or gravel. Tests[11] indicate that these materials have some isolating value, reducing the amplitude of vibration approximately $^1/_2$ to $^1/_3$. This seems to be a surface effect, the particles acting much as a mass of ball bearings. The isolating value is greater for gravel than for sand and does not seem to vary appreciably with the depth of the material.

The author has no experience with this material, but the use of a 3-in. layer of sand topped by a 9-in. layer of gravel seems to follow the dictates of good judgment. The gravel should be well tamped into the sand layer in order to reduce the settlement.

Miscellaneous Isolation Details. There are certain degrees of isolation of the engine foundation which should be incorporated in every design. The floor slab surrounding the engine foundation should never be in direct contact with the foundation. When the floor is laid on earth it should abut the foundation. It should not be supported on a shoulder, and should be separated from the foundation by an expansion joint, preferably of the sponge-rubber type. When there is a basement surrounding the engine foundation, the operating floor is generally separated from the foundation by an air gap of $^1/_4$ in. The edges of this gap are generally protected against chipping by metal edge strips which are embedded in the concrete finish course after the engine is grouted. It is important that this floor also be supported independently of the engine foundation. Furthermore, it is desirable that any columns supporting this floor be placed as far as possible from the foundation mat. The author has used cantilever floor

[8] "Influence of Damping in the Elastic Mounting of Vibrating Machines," by E. H. Hull, Trans. A.S.M.E., vol. 53, 1931, paper APM-53-12.

[11] "Noise and Vibration Engineering," by S. E. Slocum, D. Van Nostrand Company, Inc., New York, N. Y., 1931, pp. 39–41.

slabs to good advantage in these locations. A cantilever slab of say 3 ft projection is constructed as part of the engine foundation and a similar slab extends out from the surrounding beams and columns. This construction is particularly advantageous where a group of engines are set in parallel positions, since the cantilever slabs can be extended from the foundations of adjacent engines, and basement columns in the aisle between engines are eliminated.

The maximum projection for a cantilever slab should be about 3 to $3^1/_2$ ft and the slab should be of variable thickness, say 4 in. at the outside edge, and $^1/_5$ of the projecting length at the inside edge.

It is often necessary to provide removable steel floor plates spanning between the permanent floor and the engine foundation. These plates are so flexible that it is necessary to support them from the engine foundation. The connection should allow lateral motion in all directions and yet hold the plate against a vertical vibration causing rattling. Joints in this floor plate should be bolted and stiffened against vibration. Large areas or long spans should be reinforced by welded stiffeners.

Concrete—Mix–Placing–Curing

Concrete for engine foundations should be low-volume-change, high-unit-weight material. Engine foundations are always massive, hence a low-volume-change concrete is necessary to prevent cracking of the foundation. Low volume change may be accomplished by the use of low cement factor (approximately 5 sacks per cu yd, maximum), and low water content (slump not exceeding 2 in.). The use of large maximum-size coarse aggregate, low ratio of sand to rock, and uniform grading of sand and rock are important items in attaining both of these objectives. The use of low-heat cement is advantageous for very large foundations. High unit weight is of course desirable; it can be attained by the use of heavy rock of large maximum size.

The use of high-early-strength cements for engine foundations is never advisable. This class of cements universally exhibits the properties of high shrinkage and high heat evolution which invite trouble from severe cracking.

A concrete meeting the foregoing requirements will easily exceed a minimum-strength specification of 2500 psi, providing it is properly placed in the forms and adequately cured. This dry, low-slump concrete must be thoroughly compacted. The use of internal vibrators is recommended. The strength gain of Portland-cement concrete requires a certain period of time in the presence of both temperature and moisture. The setting of the cement evolves a considerable quantity of heat and will maintain proper curing temperature under all except extreme temperatures. In very cold weather, the heating of the adjacent air to say 45 F is advisable, in order to provide curing temperatures for the concrete near the surface. Adequate moisture for curing concrete is present when it is placed in the forms. The conservation of this moisture by covering exposed surfaces and leaving the form in place as long as possible is a most effective curing method. There are several liquid curing membranes on the market which are effective in sealing the concrete surfaces. The use of these is advisable if early form removal is required.

Reinforcing. Construction of concrete engine foundations without reinforcing steel is never advisable. With the exception of cantilever-footing slab, there are no calculated stresses to be carried by this reinforcing steel, but its use in nominal quantities is necessary to eliminate serious cracking completely. Cracks which would cause no concern in ordinary concrete construction are often serious in engine foundations, because the severe vibration to which they are subjected may cause progressive cracking. The author's practice is to use deformed intermediate-grade steel reinforcing bars of $^1/_2$ or $^5/_8$-in. diam, spaced on 12-in. centers, extending both vertically and horizontally near all faces of the foundation block. The size of reinforcing bars may be varied to suit the general massiveness of the foundation.

In Diesel-electric sets where the generator is mounted on the same foundation as the engine and in similar installations, there is a large reduction in the cross-sectional area of the foundation block at the flywheel pit and generator pit. At these locations and all cross sections where the area is considerably reduced, additional reinforcing amounting to say 0.75 per cent of the reduction of area should be provided.

Grouting. The use of a nonshrink grout between the engine bed and the foundation is always desirable. The one factor causing shrinkage of cement and concrete is excess water. Some excess water is necessary in order to get the grout into place, but this should be held to a minimum. The sand must be well graded with a maximum size as large as can be worked into place. Add fine gravel if the depth of grout is more than $1^1/_2$ in. This provides a minimum percentage of voids and reduces the amount of water-cement paste required. Never use a mix richer than 1:3. The addition of an expanding admix, as specially prepared powdered iron, is recommended to reduce the shrinkage further. Several brands of this material are on the market and the author feels that their cost is certainly justified.

The dry materials should be thoroughly mixed and water added slowly until the consistency becomes plastic but not soupy. It should then be placed with thorough puddling and ramming.

Vibrations Not Attributable to Faulty Foundations

Properly designed foundations are often blamed for vibrations that are actually air-borne, caused by the air columns set in motion by the engine intake and exhaust. Treatment of this subject is beyond the scope of this paper but it should always be considered in the design of a Diesel-engine installation. The use of adequate intake and exhaust silencers is the first step in eliminating this difficulty.

Locating large flimsy window areas, especially those with hinged ventilating sections, adjacent to the intake and exhaust is a practice always to be avoided. Furthermore, it is true of the entire power-plant building that the use of light flexible structural members is to be avoided. The author favors the use of rigid-frame bents instead of trusses and columns and, in general, the use of continuous construction wherever possible.

Discussion

R. D. Campbell.[12] Let us assume a case in which the ground has a fixed period of vibration, or natural frequency. On such a subsoil is placed an isolating material, springs or cork, having a period of vibration, or natural frequency, different from that of the subsoil or ground. If the engine or vibrating mass is then placed on this isolating material will the frequency of the subsoil or the frequency of the isolating material determine the effectiveness of the isolation, i.e., the amplitude and force of the transmitted vibrations?

A. F. Robertson.[13] What precautions actually have to be taken in the field when determining Δ, the deflection of the soil under static load, so that the equations given in the paper may be applied properly? Is the value of Δ determined from experience with past installations, or must static-deflection tests actually be made on the soil being used?

C. B. Rosenberg.[14] Inasmuch as most of the work cited in

[12] Shell Oil Company, Wood River, Ill. Mem. A.S.M.E.

[13] Fairbanks, Morse & Company, Beloit, Wis.

[14] The Pure Oil Company, Chicago, Ill.

the paper is based upon a consideration of the harmonics developed in multicylinder engines, the conclusions are not applicable to single-cylinder engines. What comments would the author care to make upon the installation of one-cylinder Diesel engines to minimize engine vibration?

A. L. BAYLES.[15] In connection with the mounting of a single-cylinder compressor and engine on a common base for ship service, a damping effect had to be achieved. The compressor in question had a high ratio of moving mass to fixed mass. The matter was solved ultimately by creating a fictitious mass through the process of imposing dampers acting downward as well as upward. The installation was successful.

To elaborate, what we did was to assume that the entire mass, composed of engine, compressor, and subbase, weighed more than it actually did. (In this particular case, about 2000 lb.) We then designed the lower dampers for the compression of the actual plus the fictitious load, distributed over the dampers. The top dampers were then designed to impose a load of approximately 2000 lb more to make up the deficiency of the actual load.

Would the author's formula apply in the case of a damper imposed on top as well as below? He is presuming that there is no particular "jump." In this particular case, we had a very marked upward reaction. As a matter of fact, the isolation calculated by conventional methods was perfect, but the unit oscillated badly. In this case we could not resort to the expedient of additional mass because of limitations imposed by the capacity of the ship.

W. EXLINE.[16] Where direct-connected compressing units are coupled at 90 deg with the same crankshaft as the power cylinders, we have found that an unbalanced load exists. When the engines were originally set this condition caused them to move in a horizontal plane, setting up stresses in the crankcase, which caused the grouting corners to fracture and break. Are there any types of insulation which could be used on this type of engine construction, such as springs or insulating material, to eliminate this difficulty? The reference is to units used in gasoline plants and gas-compressor stations where this particular trouble has been experienced when setting the shafts of such engines.

E. J. KATES.[17] The author has done an excellent job in preparing this scientific treatise on a subject which has been permeated with empiricism and shrouded in mystery. A few questions come to mind. One concerns the use of cork isolation. The author concludes from theoretical considerations that cork isolation "has proved very effective in insulating sound and high-frequency mechanical vibrations, but is not suited to the isolation of low-frequency mechanical vibrations, because its natural frequency is too high." However, in actual use, cork seems to be a peculiar material that does not abide by the theories now applied. The writer has observed low-speed, low-frequency units installed years ago on cork foundations, which have proved entirely satisfactory although, according to the theories developed later, the isolation should have been a failure. However, the installations did prove successful. Therefore, too great reliance should not be placed on the present theory concerning cork isolation until, after further study, the theory is corrected and made to conform more closely with experience.

Confirming statements made relating to the use of springs above vibration isolators in order to simulate additional weight, the writer has witnessed such an application to a 4-cylinder vertical engine which bounced very badly on its foundation until such springs were installed. They were very stiff springs and caused the foundation to act as if it were heavier, thus reducing the bouncing motion.

What has the author found it advisable to do for side isolation of foundations, particularly in the case of horizontal engines? Of course, with vertical engines, the best side isolation is just air. In the case of horizontal engines, where there are heavy unbalanced forces in the horizontal direction, one cannot always isolate with air, otherwise the foundation may shift.

G. C. BOYER.[18] The author mentioned the fact that some things do not work out according to theory and that applies equally, it is believed, to horizontal engines on foundation blocks. The writer recalls an experience in Oklahoma where a group of horizontal engines were installed on a concrete boat set in a marsh. According to all the vibration theory known to any of us, that plant should have been down the river 2 or 3 miles within a couple of weeks. The plant is still running in the original location, and vibration troubles are unknown.

Bear this fact in mind. When the preparation of this paper was undertaken some months ago, the only information available in our office on the subject of foundation design was what we had obtained from some of the large engine manufacturers, and that was very meager. This is not intended as criticism; rather it is the result of the lack of progress in the science of foundation design.

Too often it has been the practice to place a block of concrete in the ground, set an engine on it and, because of the fact that the soil was good, and nothing of a delicate character was around to shake, the foundation was a success. When the installation of another foundation was required, the original drawings were used again. In this case, perhaps, the soil was not so good, and the result was excessive vibration. A third installation was required, so, remembering the sad experience in the second case and in order to be on the safe side, the designer increased the size of the foundation in the hope that the addition of mass would correct the evil. It appears to the writer that the evolution of foundation design has too often been one merely of increasing the mass of the concrete block under the engine without fully evaluating all of the items which enter into the design of a successful foundation for an internal-combustion engine.

There is much concerning the design of foundations which has not been covered in this paper, but it was prepared in the hope that it would stimulate more interest in this subject, which has had so little discussion in the past. It was hoped that enough interest would be aroused in the subject so that perhaps someday we can explain some of the vagaries cited in the discussion where theoretically a design was not supposed to work and it did work; a place where dry sand was not supposed to isolate the foundation but it did; a place where a foundation on mushy soil was supposed to vibrate but did not. There must be a reason for all these contrary facts. This paper may stimulate others to try and find out some of the reasons for these contrary experiences.

AUTHOR'S CLOSURE

In answer to Mr. Campbell, the predominating factor will be the isolating material. It will still be effective, but the general effect of very soft subsoils is to reduce the efficiency of vibration isolation. In other words, the material under the vibration isolation should be fairly firm for best results. This problem is completely covered by vibration theory but is rather complicated.

In answer to Mr. Robertson, the design problem would fall

[15] Hill Diesel Engine Company, Lansing, Mich.

[16] Exline Diesel Engine Works, Kipp, Kan.

[17] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[18] Burns & McDonnell Engineering Company, Kansas City, Mo. Mem. A.S.M.E.

into one of three classifications upon visual inspection of the subsoil: (1) With a firm hard subsoil, vibration will not be an important factor and the design will be simplified; (2) with a soft subsoil the reduction of vibration will be a serious consideration and unusual care should be taken in the design; (3) with an intermediate subsoil condition, intermediate measures of design will be in order and the designer must exercise judgment in considering the various factors involved.

In the latter two cases the natural frequency of the engine and foundation will be an important factor. The natural frequency of an engine foundation can be predicted roughly from Table 1. In cases where vibration is objectionable and preliminary studies indicate an ω/p ratio greater than 0.5 the author would recommend a calculation of the natural frequency based on a field determination of Δ.

To begin with, the unit loading of the foundation on the subsoil will usually be between 1000 and 2000 lb per sq ft. If static deflections are taken for several loadings within this range, a curve can be drawn from which the deflection for the particular unit loading may be obtained. Another factor which must be taken into account is that the deflection is not the same for an area of 1 sq ft at 2000 lb load as it would be for a 200-sq-ft area loaded to 2000 lb per sq ft. However, static deflections may be taken for two or three different sized areas at the same unit loading, and the effect of the size of the area determined approximately. By the combination of these two relations, a reasonably good prediction of Δ and the natural frequency can be made.

In single-cylinder engines, as mentioned by Mr. Rosenberg there will be unbalanced forces and, in general, isolation will be quite a problem. By means of isolation, the vibration that is transmitted to surroundings may be reduced, but it is the author's belief that the unbalanced forces would be so great that the suspended foundation block would hop around considerably. Generally, in a location where vibration is very undesirable, a single-cylinder engine cannot be operated satisfactorily. If vibration is permissible to some extent, the best foundation which can be provided for a single-cylinder engine is as large a mass as can be used on a subsoil as firm and hard as can be produced.

Mr. Bayles' expedient of using springs both above and below an engine is a good one. Such an installation should behave exactly according to the formulas. The effect of the upper springs is to increase the static deflection and decrease the natural frequency.

Mr. Exline's problem is one of unbalanced horizontal forces, probably in the compressor. These forces produce a twisting moment about a vertical axis. Of course, the stress due to this moment is greatest at the corners of the foundation, and apparently, the corners were not strong enough to resist the stress. It is the author's belief that vibration isolation does not enter this problem at all.

The author has little faith in the efficiency of cork as an isolator for low-frequency vibration, although his conclusions are based mostly on theory. However, the theory is rather definitely confirmed by a number of experiments, notably those of reference 8, in the paper. Cork has been used on a number of foundation installations which probably would have worked as well without it, but the cork has received the credit.

The author has had but little experience with foundations for horizontal engines. However, it is believed that such a foundation could be very well isolated by the use of both horizontal and vertical springs. The horizontal springs should be compressed into place and would act much as those used both above and below the vertical engine cited by Mr. Bayles.

Instrumentation for Developing and Testing Diesel Engines

By C. R. MAXWELL[1] and K. M. BROWN,[1] PEORIA, ILL.

This paper gives a comprehensive idea of the range of Diesel-engine measurements essential to the design of efficient and successful types. Such measurements include accurate power determination, fuel consumption, lubricating-oil consumption, record of crankcase blow-by, exhaust-smoke measurement, all of which are items of performance. In addition, such informative items as pressures attained, rate of pressure rise, combustion analysis, flame duration, exhaust-gas analysis, functions of fuel-injection system, temperature measurements, vibration data, are all essential of determination. Descriptive details are given of the instruments and methods employed in one of the leading Diesel-engine testing laboratories of the country for the determination of these and other Diesel-engine design and operating factors.

ALTHOUGH Diesel engines are widely advertised as burning little or no fuel, having low peak pressures, running smoothly, and having other qualities, engines are bought and sold on a basis of power. Therefore the measurement of power is certainly of primary consideration. Great accuracy of power measurement may not be necessary for rating purposes or for endurance runs, but successful development of an engine is greatly facilitated by the use of accurate reliable power determinations.

Another factor of considerable importance to the buyer of a Diesel is fuel consumption. Because of its high expansion ratio, the Diesel engine converts fuel into power with a fair degree of efficiency. However, so many engine factors influence efficiency that really good fuel consumption can only be obtained as the result of considerable development. Without a good device for the measurement of fuel consumption, such development is impossible.

Due to the low fuel consumption of the Diesel engine and the considerable price differential between fuel oil and lubricating oil, oil consumption is a large factor in operating economy. Unfortunately, the rules for obtaining good oil consumption are general, at best. Consequently, oil consumption must be checked, particularly in a new design, even though the design has been based on the results of past experience. The length of time required for such tests is an inverse function of the accuracy of the measuring equipment.

As a criterion of the condition of pistons and rings, crankcase blow-by is unexcelled. No endurance test is complete without a record of blow-by. Crankcase blow-by, or more accurately piston-ring blow-by, has so many deleterious effects and so few good ones, it might easily be termed the ill wind that blows nobody good. Even an engine in excellent condition has some blow-by. In reducing this to a minimum, measuring equipment is essential.

Of late years, it would seem that everyone has become "smoke conscious." Cities are instituting smoke-prevention campaigns, legislative bodies are legislating about it, and the general public is complaining about smoke. For some time, the Diesel engineer has realized that smoke meant incomplete combustion, with consequent reduced efficiency and greater internal engine deposits. He thus finds it desirable to measure the amount of smoke given out by an engine, and particularly to be able to indicate small changes in the smoking tendency of an engine, so that he may know when he is making an improvement.

All the items that we have so far considered—power, fuel consumption, smoke—are what the engine does, or how it performs. However, to be able to improve an engine the engineer must know "why" it performs as it does. One of the most informative items that is reasonably easy of attainment is the pressure diagram or indicator card. In the old steam-engine days, the indicator card was a pressure-volume card, but the Diesel engineer finds that a pressure-time diagram gives him more information, particularly about the combustion period, which is his chief interest. One of the first things the indicator card tells him is about timing; whether combustion is starting too early or too late or is "just right." Of course, he is interested in the pressures attained, not only from the combustion standpoint, but also from the standpoint of loading on engine components, and he is particularly interested in the rate of pressure rise, which has a bearing on engine smoothness and knock. To an experienced Diesel engineer, the general shape of the card is most informative. Combustion analysis by means of logarithmic diagrams may be made from the card if desired. The card may also be used to determine indicated horsepower and turning-moment diagrams.

Another way the Diesel engineer has of determining the "why" of his engine is to observe flame duration. Also, an analysis of the exhaust gases gives him a clue as to the chemical changes going on in his engine.

The maximum usable output of a given engine depends directly on the rate of air consumption. Many engines have had their lack of performance traced directly to a deficiency in this respect. Here again, measuring equipment is essential.

It may be said that no Diesel engine is better than its fuel system. It may also be said that few engine parts or functions are more reluctant to give up their secrets. The injection of fuel is a complex phenomenon involving pressure, inertia, compressibility, wave motion, vibration, ballistics, and other factors, occurring in the space of a few milliseconds. Surely there are not many places where instrumentation may be employed to greater advantage than in the development of a fuel system.

The Diesel engine is a "heat" engine, so high temperatures are involved. The temperatures attained by certain parts may be a limiting factor in their life and performance. Particularly is this true of pistons and bearings, but these are the parts where temperatures are most difficult to measure.

Finally, we find that our engine sometimes has an unfortunate habit of shimmying and shaking more than we would like. Vibration is annoying to an operator or anyone near an engine, but it also can be the cause of excessive stresses in certain parts and result in failure of that part. One particular form of vibration which needs attention is valve-spring surge. Torsional vibra-

tion of crankshafts is often the source of noise and sometimes even of failures.

Horsepower and Fuel Consumption

The measurement of the power of a Diesel engine is today relatively simple. Dynamometers of many types are available in a wide range of sizes. Probably the best dynamometer for general development work is the Sprague-type electric dynamometer, Fig. 1. These dynamometers are essentially d-c generators with

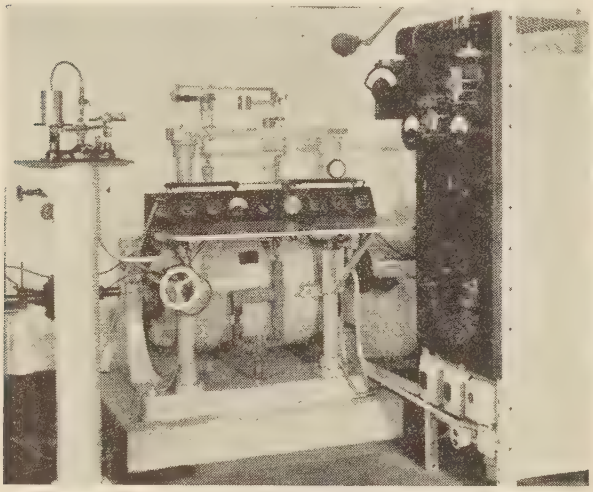

Fig. 1 Dynamometer and Fuel Scales

the stator mounted in bearings so that the torque reaction may be measured on scales. The power is absorbed by resistances or grids and dissipated as heat. Advantages over other types include ease of control and, most important, the possibility of using the dynamometer as a motor to measure friction torque directly.

A relatively new dynamometer which has gained considerable popularity in recent years is the eddy-current electric dynamometer. An iron or steel disk is rotated in a magnetic field, causing eddy currents in the disk. The power is thus converted to heat, which is carried off by a considerable flow of cooling water. The stator is cradle-mounted so that torque reaction is measured directly. These dynamometers are characterized by their large power-absorption capacity in small sizes, and simplicity of control. While they will not run as a motor, dynamometers are now available with cradle-mounted d-c motors connected in tandem for starting purposes and friction-torque measurements.

Most dynamometers measure torque directly. Horsepower being a function of torque and speed, no dynamometer can be more accurate than the means used for measuring revolutions per minute. Electric tachometers consisting of a permanent-magnet generator and voltmeter calibrated in rpm are quite reliable. Being readily adjustable, they are capable of giving accurate speed indication for years with a minimum of maintenance.

Stroboscopic devices are often used as speed indicators. By using constant-frequency alternating current for timing the flash and the proper number of equally spaced markings on a rotating engine part, a great many synchronous speeds may be obtained.

One of the earliest forms of speed-indicating devices is a revolution counter and stop watch. These two instruments have now been combined into one compact unit which automatically counts the revolutions for a given period of time and registers rpm. These have proved to be quite accurate.

An excellent device for speed measurements in engine testing is a revolution counter directly coupled to the dynamometer shaft through a solenoid-operated clutch, and an electrically operated stop watch, Fig. 2. Both are started and stopped simultaneously by a single button. The stop watch may be a solenoid-operated conventional stop watch, or some type of electric time clock. Although some maintenance may be required, results can be very satisfactory if the units are well designed.

A good counter and stop watch are essential for accurate fuel-consumption measurements. Volumetric fuel-consumption measurements may be quite easily made by installing a tee in the fuel line between the tank and engine with a valve between the tank and tee. A calibrated pipette is connected to the third branch of the tee with the overflow piped back to the tank. When the valve is shut off, the engine draws fuel from the pipette. As the fuel passes the calibration marks on the pipette a stop watch is

Fig. 2 Counter and Tachometer Drive

started and stopped. If horsepower is read at the same time, specific fuel consumption may be obtained.

Fuel consumption on a weight basis may be obtained by replacing the pipette with a small fuel container placed on one tray of a simple balance, with suitable weights on the other tray. The valve is shut off, causing the engine to draw fuel from the container. As fuel is drawn from the container the scale becomes unbalanced and trips an electrical contact which simultaneously starts the watch and counter. A weight is then removed from the scale and, when the scale again trips, the electrical contact stops the watch and counter. Thus time and total revolutions for the consumption of a given weight of fuel are obtained. If the torque is read, we have all the data necessary for a complete fuel-consumption reading. It may be of interest to point out that a specific fuel-consumption reading is not affected by watch accuracy, since it is a function of torque and total revolutions for a given weight of fuel. The watch is necessary only for rpm readings for brake-horsepower calculations.

Oil Consumption and Blow-By

Oil consumption has always been difficult to measure accurately in a short period of time. While the oil in circulation is substantially constant, the continued splash of oil being thrown from the rods and air currents set up by the whirling crankshaft, keeps the oil level in a state of extreme disturbance.

A method successfully used to overcome these difficulties is to drain the sump into an external reservoir. Oil is pumped from

this reservoir to the engine in the usual manner. The reservoir is placed on a platform scale and weighed at suitable intervals. Since the main portion of the oil is now removed from the major disturbing influences it is in a relatively quiet condition and rate of oil consumption may be determined in a few hours.

For the measurement of piston-ring blow-by, displacement meters are generally used, either the wet or dry type. Dry meters are usually preferred because of their smaller size for a given capacity. These are of the same general design as the ordinary home gas meter.

Occasionally it is desirable to read blow-by continuously so as to watch fluctuations more closely. For this purpose rate-of-flow meters are available. The most common type consists of a tapered glass tube through which the gas passes, causing a float to rise to a height determined by the rate of flow.

Smoke Measurement

The simplest method of measuring smoke is, of course, the visual method. The observer looks at the smoke and then rates it as clear, trace, light, medium, or heavy, according as his judg-

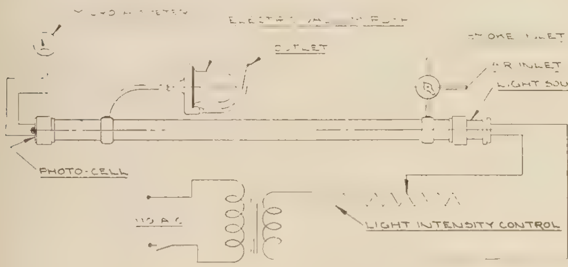

Fig. 3 Schematic Diagram of Smoke Meter

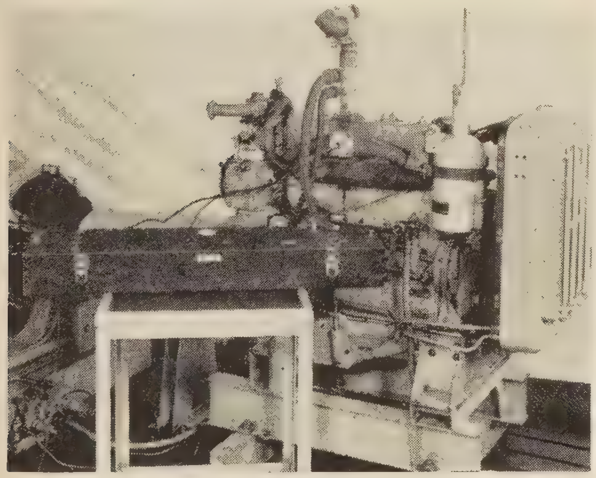

Fig. 4 Smoke Meter on Engine

ment dictates. It is obvious that a great personal factor enters into such a determination, and even an experienced observer has difficulty in judging smoke from one time to another because of changing light conditions, and because the nature of the background against which the smoke is observed influences what may be seen. In this connection, it may be noted that, when smoke is observed against a dark background, with light streaming across the column of smoke (thus viewing the smoke by reflected light), the smoke appears denser, and hence, smaller traces of smoke may be observed than when the smoke is observed by transmitted light.

A method of measuring smoke which is coming into considerable use is the sampling-type smoke meter, such as the one described in a recent paper[2] by K. M. Brown. This smoke meter, Fig. 3, consists essentially of a tube through which, by turning a two-way valve, either clean air or a continuous sample of the smoke may be drawn by means of an electric vacuum pump. At one end of the tube is a light source, the intensity of which may be controlled, and at the other end, a photoelectric cell. The method of use consists of turning the control handle so that clean

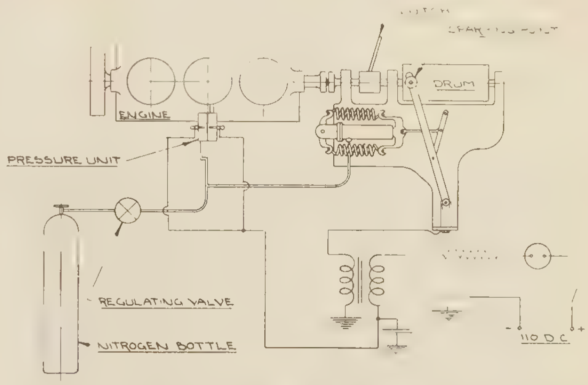

Fig. 5 Schematic Diagram of Farnboro Indicator

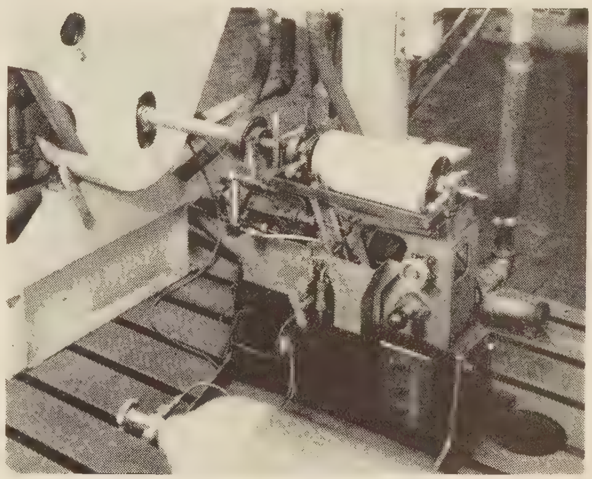

Fig. 6 Farnboro Indicator

air is drawn into the meter, and adjusting the light intensity so that a definite reading is obtained on the meter indicating the photoelectric-cell output. The control handle is then turned so that the sample of smoke is brought into the tube, thus causing the light falling on the photoelectric cell to diminish proportionally to the density of the smoke. Fig. 4 shows the smoke meter connected to an engine. These meters may be made very sensitive by increasing the length of the measuring tube.

Combustion Analysis

For slow-speed engines, the old steam-engine indicator was quite satisfactory but, for higher-speed engines, it is entirely inadequate, principally because of its excessive inertia. It has thus been necessary to develop other types of instruments to indicate cylinder pressures in medium- and high-speed Diesel en-

[2] "Requirements of a Smoke Meter," by K. M. Brown, *S.A.E. Journal*, vol. 48, no. 5, May, 1940, pp. 188–192.

gines. There are three general types now in use, i.e., the sampling type, the balanced-pressure type, and various electrical types.

The sampling type consists essentially of a mechanism similar to the old steam-engine indicator, but which may be mounted a short distance from the engine and subjected to engine-cylinder pressure through a sampling valve in the engine cylinder. The sampling valve is operated electrically and is open only for a few degrees of engine revolution. A contactor and phasing device, driven by the engine, successively open the sampling valve for a few degrees so that 720 deg of crankshaft rotation is finally covered. Thus one complete engine cycle is covered over a period of many revolutions, so that the resulting card is a composite card.

The balanced-pressure-type indicator, such as the Farnboro

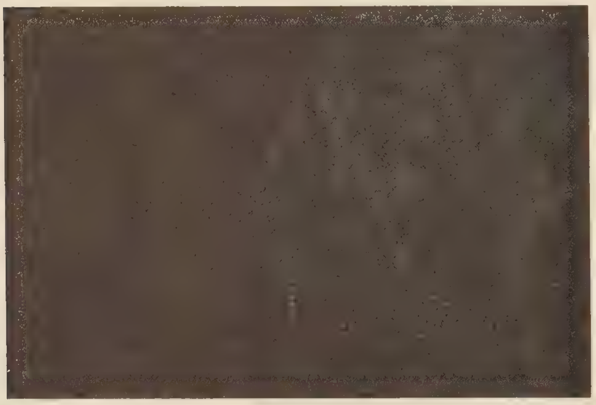

Fig. 7 Typical Farnboro Card

indicator, shown in Figs. 5 and 6, also yields a composite card but it is obtained in a somewhat different manner. The cylinder unit consists of a case containing a diaphragm which may be exposed to cylinder pressures on one side and to a controllable pressure derived from a nitrogen bottle on the other side. Electrical contacts are provided on both sides of the diaphragm. The controllable pressure is also applied to a calibrated spring-loaded piston which moves a sparking point parallel to the axis of a drum. The drum is rotated through a clutch from the engine shaft. The method of operation is as follows: Pressure is gradually applied from the nitrogen cylinder to the pressure unit and the piston operating the sparking point, causing the sparking point to move along the surface of the drum proportionally to the applied pressure. At the same time, when the cylinder pressure coming up on the compression stroke becomes greater than the applied pressure, the diaphragm in the pressure unit will move over, breaking one contact and making the other. The breaking of the contact causes a spark to jump from the sparking point to the drum, puncturing a hole in special paper which has previously been secured to the drum. When the cylinder pressure becomes just less than the applied pressure, the diaphragm moves the other way breaking the contact on the other side, so that a spark jumps to the drum at this instant. Thus, as the full range of pressures are covered, the crank angle at which the cylinder pressure equaled the applied pressure is recorded on the paper on the drum. By connecting the punctured holes, a pressure-time diagram may be drawn. Fig. 7 shows a typical diagram obtained on a Farnboro indicator.

This method is highly accurate, it gives a large-size diagram which may be easily scaled for the pressures, and is applicable to both low- and high-speed engines. It gives an average of a large number of cycles, which is an advantage if measurements from an average card are desired, but is a disadvantage if it is desired to see the cycle-to-cycle variation, or if one individual cycle is wanted. The method has one serious drawback which is that there is considerable volume in the pressure unit. In small Diesel engines, this volume is an appreciable proportion of the compression volume, so that these units cannot be applied to a small engine without changing the compression ratio.

In the last few years electrical pressure pickups of various types have come into considerable usage. They have the advantage that their inertia may be kept extremely low or negligible, so that they are usable at high frequencies. They show individual cycles and, particularly, with the advent of the cathode-ray oscillograph, they provide a quick and easily seen method of ascertaining what is going on within an engine cylinder. It is only necessary to screw the pressure pickup into its proper place in an engine cylinder, connect a few wires, and a good-size pressure diagram may be made visible on a screen. The electrical-type pickups have the common disadvantage in that they are difficult to calibrate successfully.

There are five general types of electrical pickups, i.e., the resistance type, the magnetic type, the condenser type, the piezoelectric type, and the photoelectric-cell type.

The resistance type depends upon changing the resistance of some element in an electric circuit proportionally to the change in the quantity desired to be measured. The capacity type similarly depends upon changing the capacity of a condenser.

In the magnetic type, the reluctance of a magnetic circuit is changed, thereby changing the reactance of the element, or a voltage is generated by moving a coil in a magnetic field, or changing or moving a magnetic field about a coil.

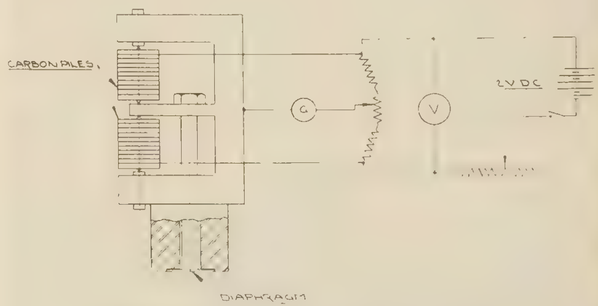

Fig. 8 Schematic Diagram of Carbon-Pile Pressure Unit

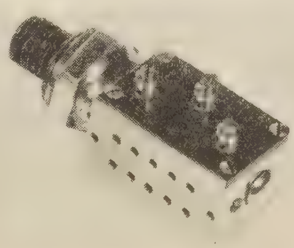

Fig. 9 Carbon-Pile Pressure Unit

The piezoelectric type depends upon the fact that changing the stress in certain crystals sets up an electrical charge on the crystal proportionally to the stress.

The photoelectric type depends upon varying the amount of light falling on a photoelectric cell proportionally to the pressure. One method of accomplishing this is by means of a diaphragm exposed to the cylinder pressures and used as a reflecting surface. As the curvature of the diaphragm changes with changes

in pressure, the amount of light falling on the photoelectric cell changes.

As an example of the resistance-type pressure pickup, the carbon-pile indicator, shown in Figs. 8 and 9, has been the most commonly used. It consists of two stacks of carbon disks placed as shown in Fig. 8 and loaded in the center by a cantilever beam. The cylinder pressures are communicated through a diaphragm and a rod to this cantilever beam. When the pressure increases, the compression on the upper stack of carbon disks is increased, thus lowering the resistance of this stack, while the compression in the lower stack is decreased, increasing its resistance. The two stacks are connected in an electrical circuit so as to form two legs of a Wheatsone bridge. The other two legs of the bridge are formed by fixed resistors with a variable resistor between them, so that the bridge may be initially balanced at atmospheric pressure. Thus, at atmospheric pressure, the resistances in the four legs of the bridge are proportional, so that the voltage across the center of the bridge is zero. When the pressure changes, the change in resistance in the two carbon-stack legs causes a voltage to appear across the center of the bridge, which may be measured by a galvanometer, or which may be applied to the grid of a radio tube and be amplified. Using the most sensitive galvanometers available suitable to the purpose only a small diagram may be obtained, so that if a large diagram is desired it is necessary to use an amplifier. The carbon-pile pickup is affected by temperature so that some cooling means must be employed. In the one shown, air is used for cooling.

Probably the most commonly used electric-type pressure pickup today is the piezoelectric type, shown in Figs. 10 and 11.

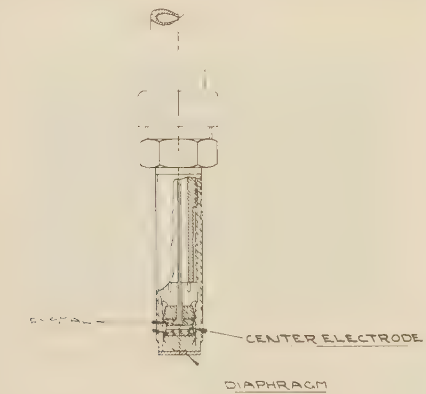

Fig. 10 Sketch of Piezoelectric Pressure Unit

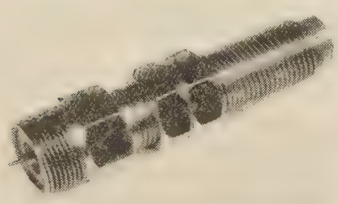

Fig. 11 Piezoelectric Pressure Unit

It consists of a stainless-steel case with a diaphragm at the bottom which is exposed to the cylinder pressures. This pressure is communicated to two quartz crystals held within the case. A center electrode between the crystals makes the external electrical connection. The application of pressure to the crystals causes them to acquire a charge. The crystals are so oriented that the charges on the two crystals are additive. If precautions are taken to prevent this charge from leaking off, the charge appears as a voltage, directly proportional to the pressure, which may be amplified and indicated on an oscillograph.

Since it is impossible to obtain perfect insulation, the charge on the crystals will have a certain time rate of leakage, so that if the pressure cycles come at too low a frequency, a certain percentage of the charge will have time enough to leak off. This fact imposes a low-frequency limitation on this type of pickup. It is stated that the error due to this cause will be less than 5 per

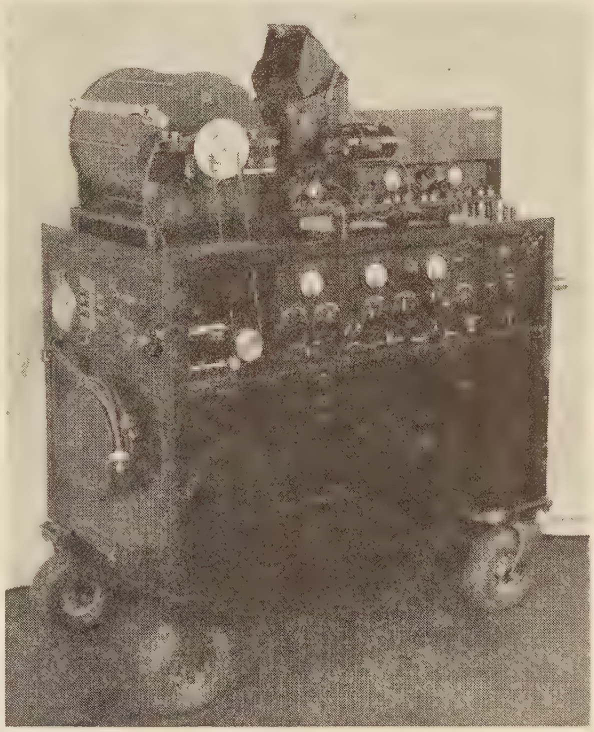

Fig. 12 Galvanometer-Type Oscillograph

cent if the speed of the engine is greater than 1200 rpm for a four-cycle engine or 600 rpm for a two-cycle engine.

For practically all types of electrical pickups the voltage output is so low that it is necessary to amplify it to obtain sufficient output to operate an oscillograph. This fact calls for some type of electronic amplifier, which brings up the question of frequency limitations. The most commonly used amplifier for this type of work is the resistance-capacity-coupled. Amplifiers of this type are built with an essentially flat response from 2 to 15,000 cycles per sec. If it is desired to amplify zero frequency, it is necessary to resort to a so-called d-c amplifier, which is straight resistance-coupled. This type of amplifier has the disadvantage of tending to be unstable.

In engine work it must be remembered that a rather large range of frequencies is encountered. In the engine-cylinder-pressure diagram, there are sometimes quite steep pressure rises, which would correspond to a very high frequency. Also the pressure diagram is essentially flat between working strokes, which condition would correspond to a low frequency—lower than the number of engine cycles per second.

So far, we have converted our pressure changes in the cylinder into voltage changes, and have amplified the voltage change to a

workable quantity. In order to make this voltage change visible, so that we can see and measure our pressure diagram, we employ the electrical engineer's oscillograph. There are two general types of oscillographs, the older galvanometer-type, and the quite common one today, i.e., the cathode-ray.

The fundamental unit in the galvanometer-type oscillograph is the elementary galvanometer, which consists of a loop of wire in a magnetic field, supporting a small mirror. When a current is passed through the loop of wire, it is deflected so that the mirror is turned through an angle proportional to the current. From a source of light, a narrow beam is focused on the small mirror. The mirror reflects it back, either onto a rotating polygon of mirrors which in turn reflects it onto a ground-glass screen, where it is visible as a moving trace of light, or onto a piece of moving photographic paper or film where a permanent record can be made. It should be noted that this type oscillograph is essentially a current-measuring machine.

The advantages of the galvanometer-type oscillograph are that in a relatively small unit four or more elements may be incorporated so that four or more simultaneous events may be observed or permanently recorded. It is thus possible to measure, easily and accurately, intervals of time between any two events. This oscillograph also has the advantage in that it will indicate low frequencies, down to zero frequency, or direct current. However, it does have a high-frequency limitation, the limit depending upon the characteristics of the galvanometer. As an example, the response of one commonly used element is flat to 1000 cycles per sec, but falls off very rapidly beyond that.

The galvanometer oscillograph is a more delicate instrument than the cathode-ray oscillograph and requires an experienced operator for its successful use. For quick, visual observation of phenomena, it is not as convenient as the cathode-ray oscillograph.

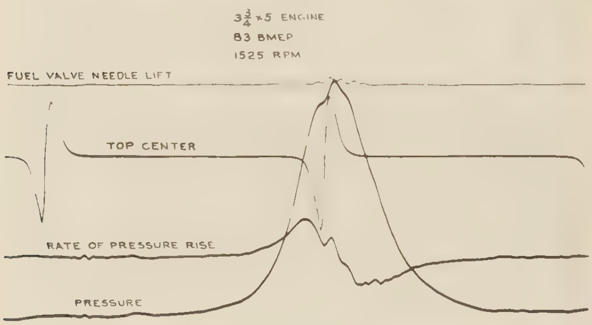

Fig. 13 Typical Record Taken on Galvanometer-Type Oscillograph

The unit shown in Fig. 12 is a four-element galvanometer-type oscillograph. Phenomena may be observed in the viewing screen B, or may be recorded on the rotating film drum shown at D. This film drum yields a record 6 in. wide $\times$ 36 in. long, and film speeds up to 40 fps are possible. A carbon-arc lamp is normally used as a source of light for this unit. As may be seen, the oscillograph and film drum are mounted on a movable buggy, which contains all the amplifiers and controls for the unit that are required.

Fig. 13 shows a typical record taken with this machine. A pressure record, a rate-of-pressure-rise diagram (obtained by differentiating electrically the pressure record), a record of the fuel-valve-needle lift, and a timing record, comprising a top and bottom dead-center mark, are included on the one diagram. It may be seen that besides the usual analyses of each individual diagram, the injection lag, the ignition lag, and the duration of injection may be obtained from this record.

The introduction of the cathode-ray oscillograph has provided a relatively inexpensive and very convenient means of observing visually any phenomena which can be converted into electrical voltage. The basic element of this oscillograph is the cathode-ray tube, a glass envelope exhausted to a high vacuum, which contains a filament or cathode to supply a source of electrons, various grids to concentrate and focus the electrons into a beam and to control its intensity, a pair each of vertical and horizontal deflecting plates, and a fluorescent screen at the end of the tube which glows when the stream of electrons strikes it, thus making their path visible. Applying suitable voltages to the deflecting plates deflects the beam of electrons proportionally to the voltages. Since a stream of electrons has extremely small inertia, the cathode-ray tube may be used at very high frequencies, considerably higher than any usually encountered in engine work.

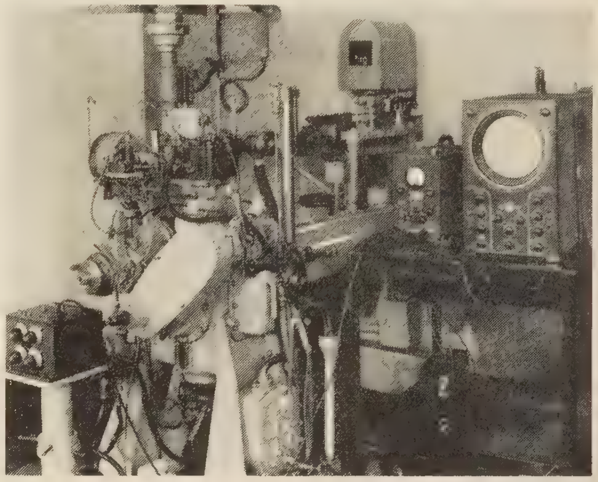

Fig. 14 Cathode-Ray Oscillograph

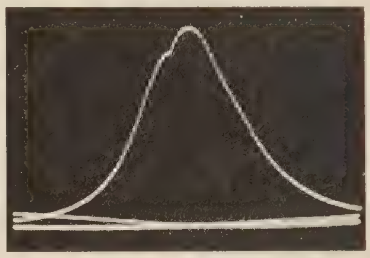

Fig. 15 Diagram Obtained on Cathode-Ray Oscillograph

The low-frequency limitation of the instrument depends upon the amplifiers used to secure sufficient voltage to operate the tube. Cathode-ray oscillographs are available, suitable for engine work, with screen diameters of 3 in., 5 in., and 9 in. The 9-in. screen provides a generous-size diagram, while the 5-in size is quite usable. Permanent records may be made of diagrams by photographing the screen with an ordinary camera. It also is possible to photograph the screen with a motion-picture camera, and thus obtain a succession of events. An arrangement has been made whereby several cathode-ray tubes have been focused on a rotating film drum, thereby obtaining simultaneous records similar to those obtained with the galvanometer oscillograph.

Fig. 14 shows a 9-in. cathode-ray oscillograph, along with an amplifier, mounted on a portable buggy, being used to obtain

pressure records from a single-cylinder test engine. Fig. 15 shows the diagram so obtained.

The advantages of the cathode-ray oscillograph are its relatively low cost, its wide frequency limits, its ease and convenience of use, and the fact that it is fairly foolproof and not easily damaged by misuse.

Its disadvantages are that it shows only a single event at a time without some rather elaborate equipment. Ordinarily it is not particularly suitable for d-c measurements, and the usual

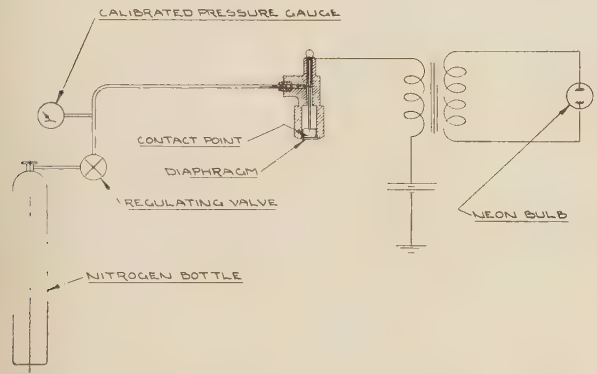

Fig. 16 Schematic Diagram of Peak-Pressure Indicator

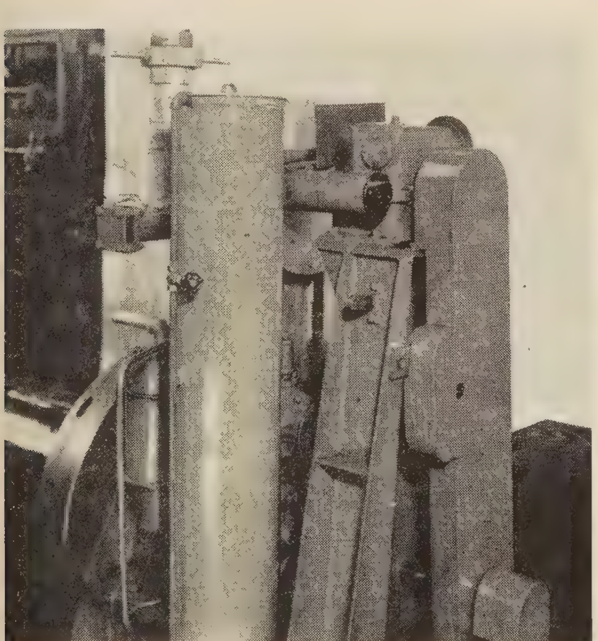

Fig. 17 Flame-Duration Setup

photographic record obtained from it is not so usable as that obtained from the galvanometer-type oscillograph.

Peak-Pressure Indicator

One disadvantage of all electrical-type pressure pickups, which has been noted, is the difficulty of obtaining a good calibration. For this reason, when it is desired to know the actual value of the pressures in an engine cylinder, resort has been made to a peak-pressure indicator which is quite accurate to give either peak compression pressures or peak explosion pressures. A device of this type is shown in Fig. 16. It is of the balanced-diaphragm type. A diaphragm is exposed on one side to the cylinder pressure and on the other side to a controllable pressure supplied from a nitrogen cylinder. A calibrated pressure gage is located in this line to measure accurately the applied pressure. There is one electrical contact in the pickup unit. When the cylinder pressure is less than the applied pressure, the diaphragm stays away from this contact. The instant the cylinder pressure becomes greater than the applied pressure, the diaphragm moves over, grounding the electrical contact, thus completing the circuit and inducing a voltage in a coil sufficient to make a neon lamp glow instantaneously. If the applied pressure is increased until it is just slightly more than the peak pressure in the cylinder, the diaphragm will not move over and the neon light will not glow. By noting the point at which a slight increase in applied pressure will cause the neon lamp to stop glowing, or a slight decrease in the pressure will just cause it to glow, the peak pressure may be quite accurately determined.

Flame Duration

Fig. 17 shows a setup that has been used to determine visually the flame duration in an engine. A quartz window is located in

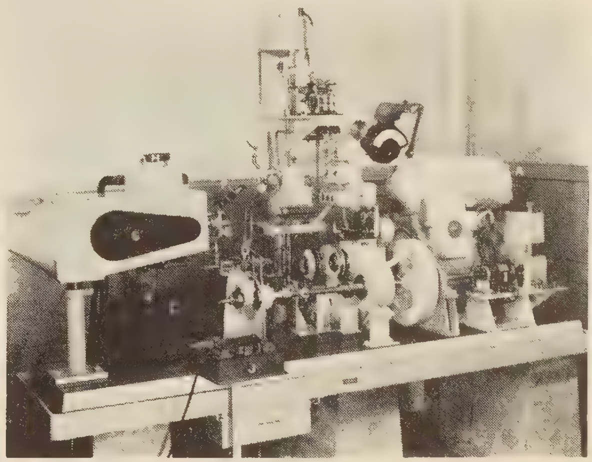

Fig. 18 Spray Machine

the engine head so that it looks into the combustion space. A stroboscopic shutter is driven from the engine crankshaft and fitted with a phase-changing device so that the quartz window may be observed for a few crankshaft degrees each cycle starting at any point in the cycle desired. A scale is provided to read the crank angle at which the shutter opens. By adjusting the phasing device so that the flame in the engine cylinder can just be seen to start, and then so it can just be seen to end, the duration of the flame may be determined.

A Diesel engine generally runs with more or less excess air, depending upon the load, or on a "lean" mixture. It has been demonstrated that most exhaust-gas analyzers are unsatisfactory at lean mixtures. For this reason, the conventional Orsat apparatus is believed to be the only satisfactory means at present of analyzing the exhaust gas of a Diesel engine.

Often in the course of engine development it becomes imperative to know the air consumption of an engine. The measurement of air flow presents so many problems that methods of measurement have been the subject of considerable discussion. Since we have no desire to precipitate further discussions on this subject, we will only say that the measurement of air flow by means of well-rounded nozzles has proved entirely satisfactory

for normal engine testing. If a few simple rules are followed, reliable results, if not hair-splitting accuracy, will be obtained.

Spray Machine

The development and testing of fuel-injection equipment is no such simple task. For this purpose a spray machine has been developed, Fig. 18. Fundamentally, this consists of a fuel cam driven by a motor and variable-speed pulleys at any speed between 15 rpm and 2400 rpm. Suitable mountings are provided for any fuel pump it is desired to test.

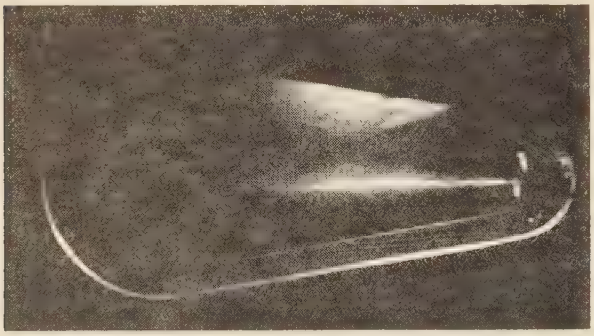

Fig. 19 Fuel Spray

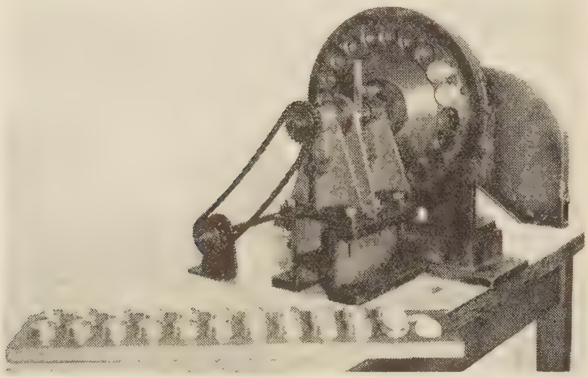

Fig. 20 Rate-of-Discharge Machine

For visual inspection of the fuel spray, a spray box is provided, one end of which has an opening for a fuel valve, the other being connected to a spray collector. The light from a high-speed stroboscope is mounted in the top of the box and one side of the box is open for the inspection of the spray. The stroboscope used is of rather simple and completely reliable design. A large condenser is charged to a potential of several thousand volts and discharged across a gap and through a neon tube when the gap is broken down by a small priming current applied by a timed contactor. The resulting flash is extremely bright and has a duration of but a few millionths of a second. By properly timing the flash, the spray may be "stopped" and examined at any point in the cycle. For taking photographs, a larger condenser is provided which gives a light of such intensity that pictures may be taken of a single flash by a camera with an *f*4.5 opening using moderately fast film. Fig. 19 shows a spray photograph taken on this machine.

For rate-of-fuel-discharge determinations, there is an attachment consisting of a disk which holds a number of light aluminum cups. The machine is so arranged that the cups are placed before the fuel valve and automatically indexed every 50 pump strokes. Blotters are placed in the bottoms of the cups to catch the spray. The spray is discharged through a slot, 1 deg in width, in a second disk, which rotates at cam speed. A third disk, placed between the other two, rotates at 0.02 cam speed and blanks off the spray for 25 injections, remaining open for 25 injections. A phase-changing gear is provided to time the slotted disk to the proper cam angle. Fig. 20 shows the machine.

The sequence of operation is as follows: First the pump cam is rotated at the desired speed and the pump is turned on. The slotted disk is then set, by means of the phase-changing gear, so that fuel is just beginning to appear through the slot, and then backed off 1 deg. Next the cups are carefully weighed and installed, after which the whole machine is set in motion. Thus, a 1-deg increment of the fuel discharge is discharged into the first cup 25 times. Then the fuel spray is blanked off for 25 injections while the next cup is automatically placed before the fuel valve, and the slotted disk is manually indexed 1 deg. Twenty-five 1-deg increments are discharged into this cup and so on until the complete fuel cycle is finished. Then the cups are again weighed, the result being a point-by-point determination of the rate of fuel discharge.

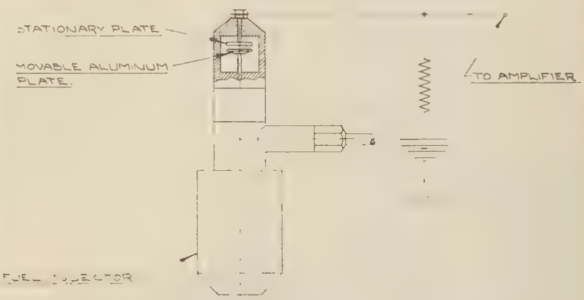

Fig. 21 Schematic Diagram of Fuel-Valve-Needle Lift Indicator

Sometimes information regarding the motion of the fuel-valve needle can be of great assistance in correcting the faults of a fuel-injection system. The simplest device for this purpose that has come to our attention is a small condenser mounted on the end of the fuel valve, Fig. 21. The plate is fixed and insulated from the fuel-valve body. The other plate is rigidly attached to the fuel-valve needle so that needle motion varies the distance between the two plates. A voltage is applied through a high resistance to the insulated plate which is connected to an amplifier having a high-impedance input circuit, the amplifier output going into an oscillograph. Since the capacity of a condenser varies inversely as the distance between the plates, and if current can be prevented from flowing in or out of the circuit, the voltage across a condenser varies inversely with the capacitance, then the voltage across the condenser will vary directly as the valve lift.

It has been found that these diagrams of fuel-valve-needle lift are very nearly proportional to the rate of fuel discharge through the valve, Fig. 22. This makes the fuel-valve lift indicator a very convenient tool for estimating fuel-discharge rate. It also has the advantage of showing differences in valve operation of successive cycles.

For the investigation of fuel-line pressure variations, a cathode-ray oscillograph using a piezoelectric pressure pickup may be used. The crystal pickup has the advantages of adding negligible volume to the fuel system and requiring minimum displacement for a given pressure indication. Its main disadvantage is its inability to register static pressures.

If it is necessary to obtain absolute values of pressure other

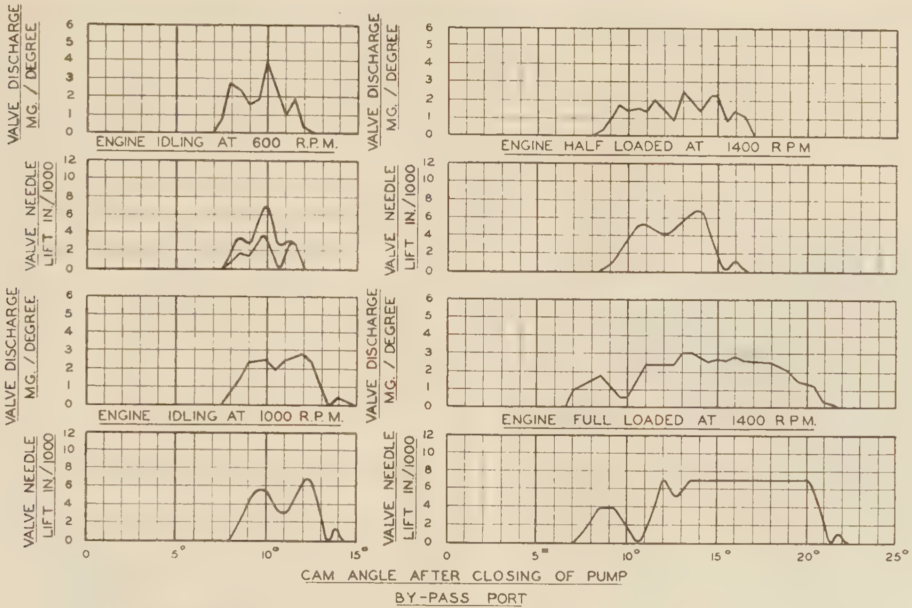

Fig. 22 Fuel-Valve-Needle Lift and Rate of Discharge

devices will have to be used. For the determination of residual fuel-line pressures a small lapped piston with a calibrated spring will give good results. The natural frequency of the spring-and-piston combination should be as high as is practical. A pin is fastened to the piston so that it extends outside the body of the instrument. The instantaneous displacement of the piston may be easily measured with a Brinnell microscope and a stroboscope. This device is hardly fast enough to register the rapid pressure variations which occur during injection, but is quite reliable for the measurement of residual pressure while the pump is not injecting fuel. The combination of these two instruments gives a very good picture of the pressures in a fuel line.

Temperatures

It is desired to know the temperature at many points on a Diesel engine, and the use of thermometers and thermocouples for obtaining temperatures on stationary parts of the engine is well known. However, the determination of temperatures on movable parts such as pistons involves some difficulties. Two methods which have been used to determine piston temperature will be discussed; both use thermocouples to indicate the temperature. The problem lies in getting the reading out of the moving piston and into a stationary meter.

Fig. 23 shows a cable device for accomplishing this result. The cable consists of a strong central cord about which is wound spirally in a flat layer (1) one thermocouple wire, (2) a silk fish line of about the same diameter as the wire, (3) the second thermocouple wire, and (4) another fish line. Over this is wound a larger-diameter fly-line in the opposite direction, and the whole enameled in place. The cable is made of sufficient length to reach from the piston and out through the side of the crankcase. To support the cable, a linkage is provided which is pivoted on the wristpin and at a point on the crankcase, with a joint in between. This linkage is so designed as to reduce the bending of the cable to a minimum.

The second means of taking the reading out of the piston involves a set of contacts so located that the contacts are made at the bottom of the piston stroke. Fig. 24 shows one type of contact which has been used. This is an adaptation of a design developed at General Motors. Here, two small contact points, one for each thermocouple lead, are fastened to the piston. These slide into two stationary contact strips fastened to the crankcase. There is a slight spring action in the stationary contacts during the sliding. Contact is made for about 50 to 60 deg of crankshaft rotation at the bottom of the stroke. The con-

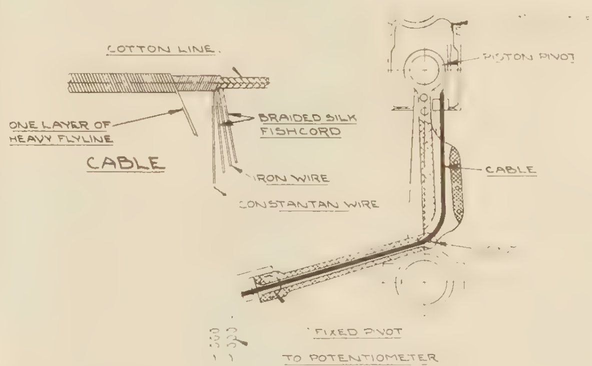

Fig. 23 Schematic Diagram of Cable-Type Piston-Temperature Indicator

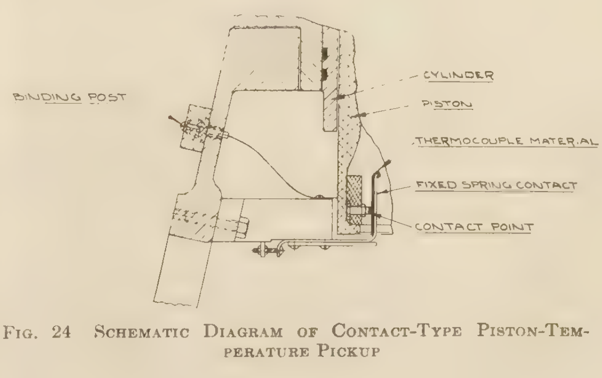

Fig. 24 Schematic Diagram of Contact-Type Piston-Temperature Pickup

tacts are covered with their respective thermocouple materials. The readings are taken with an ordinary potentiometer-type instrument. However, since the circuit is closed only about $^1/_6$ of the time, the sensitivity of the galvanometer is reduced. For this reason, it is desirable to substitute a more sensitive galvanometer for the standard instrument. If it is necessary that the contact be made for an even shorter period than this, it is possible

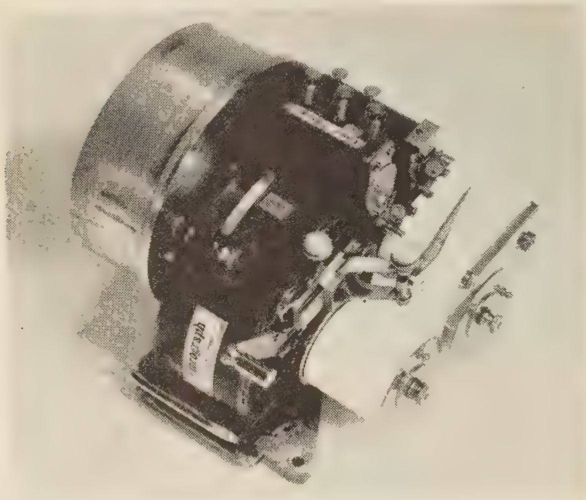

Fig. 25 Geiger Torsiograph

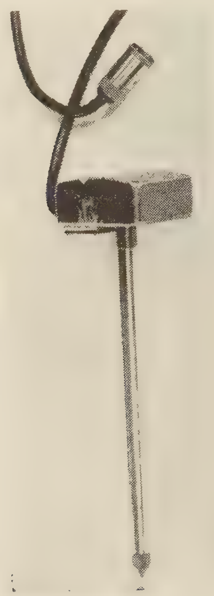

Fig. 26 Piezoelectric Vibration Pickup

to devise a circuit which will put in an adjustable compensating voltage during the open period of the contacts and to use an oscillograph to accomplish a balance between the thermocouple voltage and the compensating voltage.

Vibration

Instruments for measuring vibration, like those for pressures, may be divided into two types, mechanical and electrical. In both types there are two elements, i.e., the stationary or seismic part, and the moving part, which partakes of the motion of the vibrating body. It is then necessary to indicate the relative motion between the two parts. In the mechanical type there is a mechanical linkage between the two, which through a suitable lever system amplifies and indicates the relative motion.

Fig. 25 shows a Geiger torsiograph, used to indicate torsional vibration, which embodies these principles. A light aluminum pulley is driven from the engine crankshaft, usually by a belt, and partakes of the crankshaft motion. A relatively heavy flywheel rotates on the same shaft as the pulley and is driven from it through a light spring. The relative value of the mass and spring constant are such that the natural frequency of the system is quite low. This flywheel, then, is the seismic mass and attains the average velocity of the crankshaft. Between the pulley

Fig. 27 Magnetic-Type Vibration Pickup

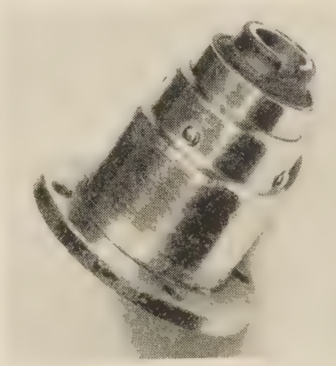

Fig. 28 Magnetic-Type Torsional-Vibration Pickup

and the flywheel there is a lever system, which amplifies any relative motion between the two and moves a recording pen across a moving tape driven by clockwork.

This instrument is most suitable for low-speed engines. With the older-type instruments, belt-driven, the results are questionable above a vibration frequency of 3000 cycles per min. With the most recent design, it is claimed to be good up to 5000 cycles per min.

In general, the electrical vibration pickups are of the same basic principles as the electric pressure pickups, and they can be classified into the same five general types, i.e., resistance, magnetic, condenser, piezoelectric, and photoelectric. A few of the most important commercially available types will be discussed.

Fig. 26 shows a piezoelectric vibration pickup. The prod on the case is held directly against the vibrating body, or the case may be fastened directly to the vibrating body. Inside the case is a Rochelle-salt crystal, supported at one edge. This type of mounting gives an inertia loading of the crystal; so the output of the pickup is proportional to the vibration acceleration. This output may be integrated to give the vibration velocity, or integrated twice to give the displacement. In the last case, unless the vibration is rather severe, there is apt to be not a great deal left of the output after two integrations. The output of this pickup is affected by temperature; in engine work, this fact may cause difficulties.

Fig. 27 shows a magnetic-type pickup for linear vibration. In this instance, the case is intended to be held stationary and the prod partakes of the motion of the vibrating body. The case contains a permanent magnet, while the prod actuates a small coil which is supported by light springs in the case. The movement of the coil in the magnetic field produces a voltage proportional to the vibration velocity. If displacement is desired, the output may be integrated once. To give linear response at low frequencies, the natural frequency of the coil assembly must be low. The pickup illustrated is supposed to be good down to 10 cycles per sec.

Fig. 28 shows a torsional-vibration pickup of the magnetic type. It is of the same fundamental principle as the linear magnetic-type pickup, but differs in the detailed construction. The case fastens directly onto the crankshaft and partakes of its motion. A permanent magnet is supported on a concentric shaft within the case, and acts as the seismic mass. The magnetic attraction of the magnet and pole pieces in the case act as the weak spring to drive the magnet mass. The coils are fastened in the case. The output is taken out through a brush in the center of the case. The output of this unit is again proportional to the vibration velocity, and if the displacement is desired, it must be integrated. This unit has been found very suitable for medium- and high-speed engines.

A resistance-type instrument, which is generally used as a strain gage, but may be used to indicate vibration, consists of a fine wire of special alloy embedded in a thin plastic. When fastened to a part that is strained, the slight elongation of the wire changes its resistance. By incorporating this in a suitable circuit the actual displacements may be indicated.

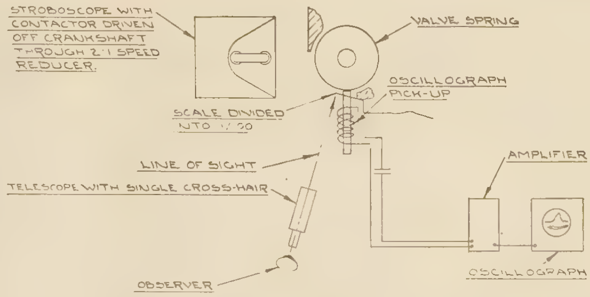

Fig. 29 Schematic Diagram of Setup Used to Study Valve-Spring Surge

All of these electric vibration pickups require the same amplifiers and indicating means, such as the oscillographs discussed under the electric pressure pickups. However, if an average value of the magnitude of the vibration is all that is desired, an output meter may be substituted for the oscillograph. We generally use the oscillograph though, as it gives us more information, showing not only magnitude, but also frequency and wave form. It is also possible to determine phase angles with the oscillograph.

A setup to study the particular problem of valve-spring surge is illustrated in Fig. 29. In order to be able to pick out resonant speeds easily, a magnetic-type pickup was located close to the center of the valve spring. This was a very simple unit consisting only of a small permanent bar magnet, with a coil of wire wound around it. The output of this was amplified and indicated on a cathode-ray oscillograph. By watching the diagram on the screen of the oscillograph, it was very easy to pick out critical speeds. To measure actual displacements of the valve-spring vibration, a scale was set alongside the valve spring, and a stroboscopic light timed by the engine itself was flashed on the spring and scale. The crank angle at which the light flashed was under the control of the observer, who, looking through a telescope at the spring and scale, could pick out the point of maximum displacement and read it on the scale.

Conclusion

Undoubtedly, there are a great number of instruments of inestimable value, which have not been mentioned here. However, since the methods of developing Diesel engines are continually in a state of flux, we have thought it prudent to confine these observations to instrumentation in everyday use in one particular laboratory.

Internal-Combustion-Engine Casualty Experience

By H. J. VANDER EB,[1] HARTFORD, CONN.

THIS paper is based on a survey of accidental breakdowns of oil and gas engines, experienced by The Hartford Steam Boiler Inspection and Insurance Company during the years 1938, 1939, and 1940. The company specializes in power-plant insurance and breakdown prevention, and covers the great majority of insured oil and gas engines. It is hoped that the compilation of accident data in the tables may contribute in some degree toward efforts to lower the accident frequency on internal-combustion engines and thus further improve their reliability.

The three-year experience of 413 accidents compiled in Table 1 covers approximately 1450 engine-years.

Of the 413 accidental breakdowns, 65 were on gas and gasoline engines, 167 on two-stroke-cycle oil engines, and 181 on four-stroke-cycle oil engines. The total amount of losses in these accidental breakdowns was $142,400.

Table 2 is an analysis by type of accident with respect to the "initial part broken or damaged." In the summation of the "initial part broken" in Table 2, the actual number of such parts involved in each accident was not used. Instead of this, the numbers of the various items in Table 2 are the number of accidental-breakdown cases in which the "initial part broken" was the principal source of the trouble. For instance, the number opposite "main bearing" is the number of cases where one or more main bearings failed.

There has been a gradual improvement in the accident frequency during the last several years. It will be noted from the totals in Table 2 that the number of accidents decreased from year to year.

Table 3 gives the accident frequencies for 10 years. The figures in this table, such as 1:2.3, mean that there was one accidental breakdown for each 2.3 engines during the year.

As a comparison, it may be stated that for steam engines the accident frequency is about 1:11.

An accident to an internal-combustion engine is defined in the insurance policy as follows:

> Accident shall mean a sudden and accidental breaking, deforming, burning out, or rupturing of the object or any part thereof, which manifests itself at the time of its occurrence by immediately preventing continued operation or by immediately impairing the functions of the object and which necessitates repair or replacement before its operation can be resumed or its functions restored, but the breaking, deforming, burning, or rupturing of any exhaust valve, valve spring, gasket, or gland packing shall not constitute an accident, nor shall the depletion of material in any part of the object, due to pitting, corrosion, or wear, be construed as an accident.

From this definition it will be noted that any sudden breakdowns of the engine or its parts (with minor exceptions) are covered by insurance. It is not the intention to cover defects that are found by inspection, such as slow progressive cracks, although the affected part might, at that time or later, need replacement, or any troubles that are clearly of a maintenance character.

Referring to Table 2, the crankshaft breakdown cases are 2.2 per cent of the total number of accidents. This is quite favorable as compared with previous experience. During 1940 not a single crankshaft case occurred which is a record. This favorable crankshaft experience is, undoubtedly, to a large extent, the result of painstaking inspection by means of a strain gage designed by the company.

The bearing troubles, 31 per cent of the total, run fairly true to previous experience. For many years, the bearing-failure accidents in internal-combustion engines have roughly amounted to one in every three accidents. Practically, no improvement can be reported. The principal causes of bearing failures were improper attention to the lubricating systems and unduly rapid sludging of the oil. Overloading also appears to have been a considerable factor in the bearing failures. More than half of the bearing failures were on crank bearings.

The cases of cylinder heads, cylinders, and cylinder liners combined, amounted to 21.8 per cent of the total. This is a somewhat lower ratio than it has been formerly. The last previous survey showed 24.3 per cent for the combined cases of cylinder heads, cylinders, and cylinder liners. Also the piston cases, 14 per cent, are fewer as compared with previous accident surveys. The fuel-pump and spray-nozzle cases, 5.4 per cent, are slightly higher than formerly.

The connecting-rod and crank-bolt accidents, 1.9 per cent, are well below previous averages. In miscellaneous accidents, 13.5 per cent of the total, are included camshafts, gears, rocker arms, valves, flywheels, clutches, water pumps, and also such parts as give trouble very rarely.

A careful review of all the experience has clearly brought out the advantages of the dual-circuit type of closed cooling system as compared with the various types of open cooling systems. A much lower premium is charged (about 40 per cent less) for insuring engines with closed systems than for engines with open cooling systems. These lower premium rates have been in use for five years and the result has been that the ratio between numbers of insured engines with closed systems and those with open systems has changed, during the last three years alone, from 50–50 to 65–35.

This change to closed systems has been a big factor in the improved accidental-breakdown experience.

Discussion

H. S. Kilby.[2] Does the 40 per cent increase in premium on open systems apply where there is an adequate clean soft-water supply?

T. M. Robie.[3] No doubt the author will agree that accidents in steam plants, because of large capacity of steam under pressure, are likely to be much more serious, in so far as human life is concerned, than accidents with Diesel plants of similar sizes. Conceivably the monetary loss would also be greater in the case of the former.

In view of the accident-frequency ratio of 1 to 11 for steam plants versus 1 to 3.5 for Diesel, it would be informative if the author will supply the corresponding ratios of financial loss involved. The writer is familiar with many of the Diesel-engine accident cases cited by the author. It would be interesting to have him supply the case histories of typical accidents in order to demonstrate the things to avoid in making Diesel installations. In cases known to the writer, the fault was chargeable to improper installation and not in any degree to design or workmanship.

The author's reaction to the closed cooling system is gratifying to the writer, since his company has been a consistent advocate of the system. This opinion is also shared widely by other engine manufacturers. We now insist that closed-type cooling be incorporated in all of our installations.

The author might explain Table 3 somewhat more fully. The writer does not of course know how many engines were being insured in 1931, or their average age, but would guess that the average age of those insured in 1940 is considerably greater than those in 1931. Actually, greater improvements have been made in the design of newer engines than the ratio shown in the table would indicate. In other words, the assumption is being made,

[2] The Kansas Power Company, Great Bend, Kan.
[3] Fairbanks, Morse & Company, Chicago, Ill.

perhaps erroneously, that many of the engines which were insured in 1931 are still insured, 10 years later. Hence, a better operating record necessarily would have to be made by the newer engines to offset the greater age of the older ones.

H. S. Crosby.[4] The writer's company operates a number of engines at various points in the Southwest, on which no insurance against mechanical failure is carried. That is definitely contrary to the policy of the company toward insurance in general. Several occasions have arisen in which we have checked the cost of insurance against our opinion as to our operating records and in each instance could form no justification for asking the company to pay the insurance premiums. We reached the conclusion that insurance coverage in the field of engine operation is in a different category from other types of insurance.

It occurred to us that what appeared to be an unusually high cost might be due either to lack of volume for the insurance companies in this field or to an unusually greater percentage of relatively poor risks. In this connection, it should be pointed out that we do not consider ourselves any better than average operators, and in many ways we are probably less successful than firms operating a larger amount of engine capacity.

Frankly, it would be desirable for our company to carry engine-breakdown insurance, and so we would be interested in determining whether there is any special approach to this problem which might lead to lower premiums. Possibly, there is some procedure in classifying types of risk with which we are not familiar. It has also occurred to us that there might be some possibility in using a relatively high deductible clause. Finally, we would be definitely interested in encouraging a larger volume of engine insurance if such an increased volume would lower the premium.

V. L. Maleev.[5] What is the difference between rates in a low classification and the highest classification? Also, in each classification are the rates constant in each group or does the rate depend upon the size of the engine, that is, is there a sliding scale for larger engines and vice versa? The author remarked that his company does not encourage the use of electric welding for repairing crankshafts. What would be the attitude toward crankshafts made entirely by electric welding instead of forging? Such crankshafts are being made in Europe and possibly will soon be made here.

R. D. Campbell.[6] An accident-frequency ratio of 1 to 11 for steam engines is mentioned in the paper, which presumably is for the engine alone. Is there a composite accident-frequency factor covering the engines, the boiler, and any other piece of the steam-plant equipment which might cause a shutdown? A Diesel engine is more or less a self-contained unit and may be treated as such. The composite factor in relation to steam plants is of importance, since it is believed that the boiler probably causes as many shutdowns as does the engine.

In connection with the cooling system, the author mentioned that in writing insurance a certain water quantity was required, presumably so many gallons per horsepower; also a certain limit is placed on temperature rise. Allowing a 20 F rise, is a rise of 150 to 170 F just as acceptable as a rise from 50 to 70 F?

E. J. Kates.[7] The writer questions whether the accident-frequency ratio of 1 to 3.5 in 1940, reported in the paper, is typical. Even though this ratio is a considerable improvement over those for 1932 and 1933, it would indicate, if typical, that the average engine is likely to suffer an accidental breakdown every $3^1/_2$ years. Such a performance record would be deemed far below average by most persons conversant with Diesel-engine operation. The cause of this inconsistency is probably that many well-run Diesel plants are not being insured; consequently, the accident-frequency ratio of the insured plants is not so good as the average. However, in the writer's opinion, the author's data are exceedingly useful.

E. C. Cole.[8] Does it make any difference whether or not an installation is fitted with alarm devices, such as are used in modern plants? Will the author also supply a definition for the term, "consequential damage?" For instance, a pin could shear off which might break the pump which in turn might burn the bearings out, which in turn might cause a complete collapse of the machine. Where does "consequential damage" stop?

Author's Closure

Diesel-engine risks with open cooling systems are rated regardless of the quality of the cooling water. The quality of the cooling water is a very important factor in the desirability of the risk on engines with open cooling systems. If the quality of the cooling water is such that an undue amount of scale is formed in the jackets, such engines may be found uninsurable. Aside from the quality of the cooling water, it has been found that the open system gives greater exposure to piston seizures and bearing failures, which apparently is due to the fact that a sudden considerable temperature drop of the inlet water is far more prevalent with the open system than with the closed system. The premium-rate differential between engines with open systems and those having closed systems is based upon loss experience.

The capacity of steam under pressure in steam-engine plants has its own peculiar hazard which is difficult to compare with the exposure to serious accidents in Diesel plants. Also, the comparative danger to human life is difficult to evaluate, in these two categories of plants. The explosion of the steam generator is to a considerable extent paralleled by the explosion of air systems and crankcase explosion in the Diesel plant. The author is not prepared to supply the corresponding financial losses. The results of Diesel-breakdown accidents, shown in the tables in the paper, speak for themselves. Unquestionably, many accidents are chargeable to faulty installation, particularly as regards the cooling system.

The average age of insured Diesel engines has not varied greatly from year to year. In 1931, the average age was approximately the same. With good inspection and maintenance (referred to later), the accident frequency of the older engines is not greatly different from that of the newer engines. While the author is of the opinion that progress in engine design has had its effect on reducing breakdown accidents, the improvement in the accident frequency, as given in Table 3 of the paper, has been mainly the result of the conversion from the open to the closed cooling system.

The accident frequency of 1:11 for steam engines, as mentioned in the paper, is for the engines alone. No composite accident frequency covering steam engines, boilers, and other steam-plant equipment is available.

The group of insured engines is a cross section of the best obtainable operating practices. Engines in poor condition or where the operating conditions are subnormal are not insurable. The insurance experience has been compared with the experience reported for a similar large group of engines which indicated a somewhat higher frequency of accident for the latter group. In

judging the cost of Diesel-engine insurance, the fact is frequently overlooked that, in the payments of losses, there enters unavoidably a large amount of money that would ordinarily be charged to maintenance if the accidents had not happened. In other words when accidental breakdowns occur to insured engines the normal maintenance account is considerably helped out by the replacement with the new parts incident to the accidental occurrence.

Diesel-engine risks are grouped in four different industrial classifications, in accordance with the different exposures to breakdown in these groups. The cost of insurance in the lowest classification is approximately double that of the highest classification. The engines are rated by horsepower capacity. There is a provision for premium reduction under an agreed deductible amount for each accident.

In judging the reported accident frequency of 1:3.5, it must be remembered that the definition of accident is quite broad and it is not merely confined to the catastrophic type of accident, but covers sudden bearing failures and practically every sudden failure of or damage to small parts. As already pointed out, there is no basis for assuming that insured engines are of an inferior class or subject to poor operating conditions.

There is no experience in this country with crankshafts which are fabricated by fusion welding, such as were mentioned as being made in Europe. The reference to welding on crankshafts is based on adverse experience where worn shafts were built up with fusion welding. This, as a rule, causes crack formation in the built-up surfaces and ultimately complete breaking of the shaft.

The recommended minimum quantity of cooling water for Diesel engines is 20 gal per hp-hr. The recommended maximum temperature rise through the cooling jackets is 20 F. Obviously, a low temperature rise means that there is good circulation of water over the hot spots, such as around exhaust valves and exhaust ports. It is not recommended that one be guided entirely by a favorable low temperature rise because of the fact that this may be the result of a badly scaled-up cylinder jacket.

There is no differentiation in the cost of engine-breakdown insurance for the use of alarms or automatic shutdown devices. Such devices are very useful if they are kept in good reliable operating condition at all times. They are, therefore, strongly recommended, and in some installations their use is insisted upon.

Consequential damage insurance is a form of coverage having to do with spoilage of goods due to lack of power or refrigeration, caused by the breakdown of insured engines or other power-plant equipment. The direct-damage-insurance coverage comprises the complete damage resulting from an accidental occurrence, as given in the accident definition. It does not merely stop with the initial part broken, but takes care of all the subsequent damage to the engine resulting from the breakage of the initial broken part.

Earlier in this closure the matter of good maintenance practice was mentioned. The recommended maintenance routine should include the examination and overhaul of vital parts at intervals in accordance with the following schedule:

Parts involved:	Operating period, hr
Spray nozzles	1250
Pistons and piston rings in 2-cycle crankcase-scavenging engines	3000–3500
Checking of exhaust-port bridges and relieving of them in 2-cycle engines	3000–3500
Piston and piston rings in 2-cycle engines with scavenging pump, and in 4-cycle engines	5000–6000
Exhaust valves of 4-cycle engines	1600–2500
Fuel pumps and fuel systems	4000–5000
Lubricating-oil pumps and systems	4000–5000

In order to secure reasonably long life of pistons and piston rings, the recommended maximum exhaust temperature for full-load conditions on 2-cycle crankcase-scavenging engines is 400 F; for 2-cycle engines with scavenging pump or blower, 550 F; for 4 cycle engines, 750 F.

Hydraulic Characteristics of Fuel-Injection Nozzles

By O. F. ZAHN,[1] MARTINEZ, CALIF.

This paper makes use of both new and previously published material in studying the hydraulic actions and limitations of fuel-injection nozzles. The primary function, hydraulically, of such a nozzle is to inject all portions of the fuel at velocities above a certain minimum necessary for atomization. The most serious factor tending to prevent this is the wide range of speeds found in present small Diesel engines. It is found that the closed nozzle meets the requirements of speed flexibility better than the simple open type, and that the variable-area-orifice closed nozzle is a further improvement over the plain-hole closed nozzle. The effects on the rate of injection and minimum regular quantity of injection are noted.

The high-speed Diesel engines of today have top speeds about 3 times those of 10 years ago, and their size has shrunk accordingly. As idling and cranking speeds, on the other hand, have increased little if at all, today's engine is far more flexible than formerly. It is this flexibility, rather than high speed in itself, which is the dominant problem facing the designer of fuel-injection equipment. Small size has resulted in idling quantities of less than 10 mm³ per injection being required; this too has made the requirements of injection more exacting than they were a decade ago. This paper attempts to discuss the newer problems of injection as they pertain to that part of the injection system called the nozzle or spray valve.

The basic hydraulic equation in injection design is that derived from the familiar Torricelli law

$$Q = A \times t \times V = c_d \times A \times t \sqrt{\frac{2g(EIP)}{d}}$$

in which

Q = quantity of injection
A = orifice area
t = time duration of injection
V = jet velocity
c_d = coefficient of discharge
EIP = effective injection pressure
d = specific weight of fuel

It has been demonstrated in rather classic tests by Lee (1)[2] that atomization depends primarily on V, and hence largely on pressure, Fig. 1, and also that it becomes finer with smaller orifice areas, Fig. 2. How are these factors affected by flexibility requirements?

Effect of Atomization on Flexibility

Let us take the case of a typical present-day Diesel engine which idles at 400 rpm and pulls peak power at 2400 rpm. Suppose that the coarsest permissible atomization corresponds to an *EIP* of 1400 psi, which is a workable minimum in most Diesels. Then, with the timed-pump system normally used on such an engine (common rail systems not being used commercially on engines having this speed range), the orifice area A must be small enough so that this pressure is obtained at 400 rpm if the nozzle is of the simple, open type. If then the *EIP* at 400 rpm is 1400 psi, what is the pressure at 2400 rpm? There are two alternatives:

1 If the compressibility of the system is negligible the velocity is 6 times as great and the *EIP* 36 times as great, or 50,400 psi. Thus, unit-injection systems, because of their low fuel volumes, are characterized by high top-speed pressures. In this case 50,400 psi is obviously higher than needed if only 1400 psi is sufficient at idling. The disadvantage of such a pressure is that a heavy, well-built system is required and the power used to drive the pump is considerable.

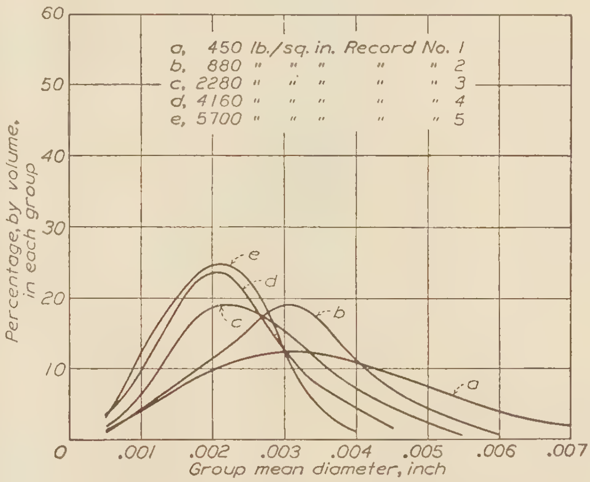

Fig. 1 Effect of Spray Velocity on Drop Size
(The velocity was varied by changing the mean pressure.)

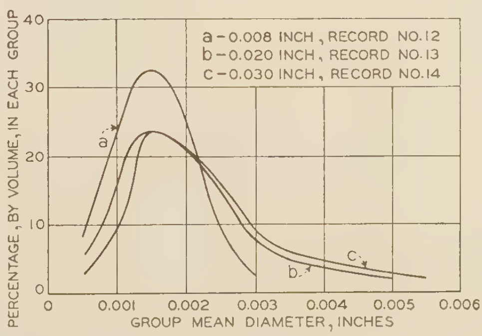

Fig. 2 Effect of Orifice Diameter on Drop Size

2 When compressibility is present, and of course it always is to some extent, the jet velocity at top speed is less than 6 times as great. This means that the time duration t is then greater than

(Variable-orifice closed nozzle with centrifugal spray; orifice and valve combined.)

$^1/_6$ for the same quantity, so that the angular duration of injection is longer at the higher speed. In such a case, the designer is confronted not with excessive pressures but excessive durations.

A closed nozzle, in which the *EIP* is determined not only by the orifice but also by a spring-loaded valve, tends to obviate both effects of changing speed. In the engine example such a nozzle might be used in which the orifice area is large enough to give a top-speed pressure of, say, only 4000 psi and no more than the desired duration, relying entirely upon the valve at low speeds. The "valve-closing pressure" (*VCP*) could be set at 1400 psi to maintain the minimum jet-velocity requirements at 400 rpm. A nozzle valve can do this, ideally, providing the nozzle is truly of the closed type and not an open nozzle with a check valve.

It is sometimes thought that valve differential is a distinguishing feature of the closed nozzle. The ratio of *VCP*/*VOP* in commercial closed nozzles varies from 0.6 to 0.9. Actually there are designs of open nozzles whose check valves also have differential. The basic criterion of a closed nozzle is that the fuel acts on its valve in only one direction. The nozzle shown diagrammatically in Fig. 3, without the dashed passage, is a closed nozzle. When the valve is open, the *EIP* is the full amount of the pipe pressure. If, however, the spring space is sealed to the outside and fuel is admitted through the dashed passage to this space, the valve becomes a check valve, and the nozzle an open one. A check valve is a pressure-reducing valve, and the *EIP* then becomes less than the pipe pressure by the amount of the *VCP* of the valve. The design of Fig. 4 is a closed nozzle even though it has no pressure-sealing lapped fits because here again pressure acts on the valve in only one direction.

When the *VCP* of a closed nozzle with fixed orifice area is higher than the *EIP* given by the Torricelli law, the instantaneous rate of injection is higher than the rate of delivery from the pump, so that the valve opens and closes more than once each injection. This action is shown in the lower curve of Fig. 5, from the work of Gelalles and Marsh (2). It is to be noted that the duration at both 215 and 470 rpm is practically the same but that at higher speeds, where the orifice area controls the pressure, the duration increases. Had the orifice been appreciably larger, the top-speed duration would have been shortened, and intermittent injection would have occurred up to a higher speed. There seems to be no evidence that such intermittent injection in itself is harmful to engine operation, but there is every indication that the accompanying valve action is detrimental to atomization.

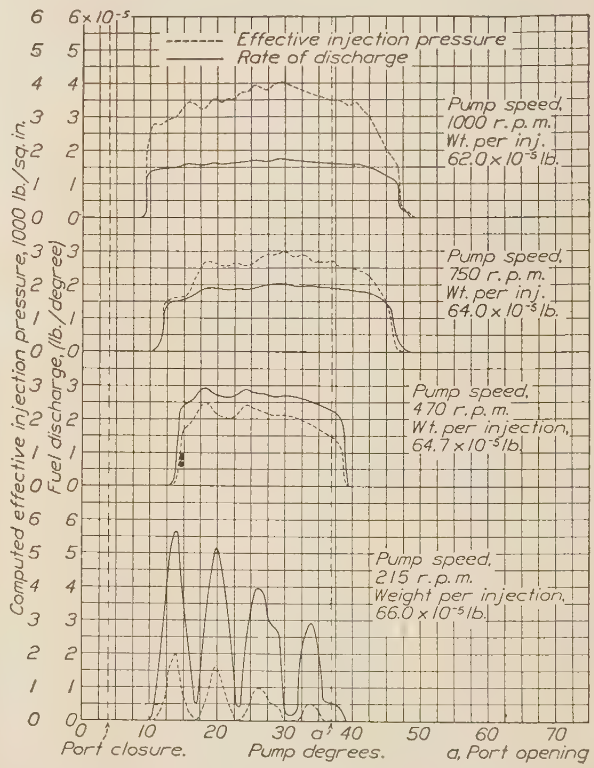

Fig. 5 Effect of Pump Speed on Duration, Rate of Injection, and Pressure

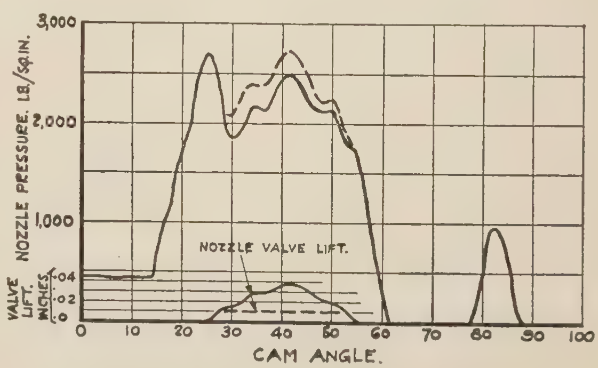

Fig. 6 Effect of Limiting Nozzle-Valve-Stem Lift
(Differential ratio 0.65.)

One action of the valve is its displacement. Considering the closed design in Fig. 3, it is obvious that each time the stem lifts it reduces the *EIP* momentarily by increasing the volume of fuel under pressure. Fig. 6 is an interesting test reported by Davies and Rowe (3), showing how the reduced limit of the valve-stem lift increased the injection pressure in the pipe. To be noted is the sudden fall of pressure when the valve first started to lift. Stem displacement reduced the pressure, and limiting the displacement limited the reduction.

Another action of the valve is its throttling or "wire drawing" in which the pressure drop occurs across the valve instead of through the orifice. In the closed design in Fig. 3, it is clear that, up to a certain lift of the valve, its area is actually less than that of the orifice. A representation of the flow conditions in a closed

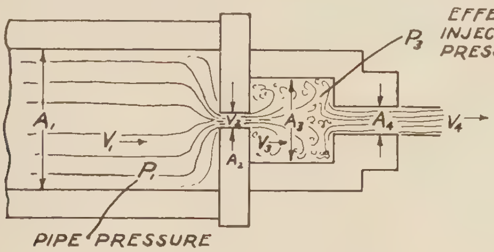

Fig. 7 Valve Throttling in Closed Nozzle

nozzle when the valve is but partially open is shown in Fig. 7. Let A_1 be the area of the section ahead of the valve, A_2 the flow area between the valve seats, A_3 the area of the section below the valve, and A_4 the orifice area. The term P_1 is the pipe pressure and P_3 the *EIP* behind the orifice. With the valve slightly open, P_3 is still almost zero and the full pressure drop of P_1 occurs in the valve A_2. Expressed mathematically, and assuming that A_1 is large enough so that V_1 may be neglected, the equation is

$$V_2 = c_v \sqrt{\frac{2g(P_1 - P_3)}{d}} = c_v \sqrt{\frac{2gP_1}{d}}$$

This velocity is dissipated in frictional heat in section A_3. Term P_3 remains practically zero, the loss of pressure P_L being given by (4)

$$P_L = \frac{K(V_2 - V_3)^2 d}{2g}$$

where K is a factor near 1. Assuming that A_3 is large and V_3 is negligible, P_L then becomes P_1. Under such assumptions, all the pipe pressure is lost in valve throttling.

The smaller the orifice area, the less this loss will be. Since

$$V_2 A_2 = V_4 A_4$$

it is possible to reduce V_2 by reducing A_4, and this will reduce P_L in the preceding equation. This analysis explains why, in Fig. 2, the 0.008-in-diam orifice showed more small drops and fewer large ones, even though the calculated mean pressure acting on the over-all stem area was 3913 psi in all three curves.

Gelalles (5) has reported that there was no throttling apparent when the valve lift was 0.005 in., which with some orifices was a valve area of only twice the orifice area. In connection with Fig. 6, the investigators stated that there was throttling when the lift limit was decreased to 0.006 in. As previously shown, the greater the orifice area, the greater will be the lift below which throttling occurs but, moreover, the greater will be the number of openings and closings of the valve at low speeds. Thus, for reasons of throttling and stem displacement there is a practical maximum limit of the orifice area which may be advantageously used in a closed nozzle.

Orifice-Area Limitations

There is some experimental evidence that orifice area influences the minimum regular quantity which can be regularly injected with a closed nozzle, as shown in Fig. 8. With a given *VOP*, *VCP*, and volume of high-pressure fuel, it thus seems of value to

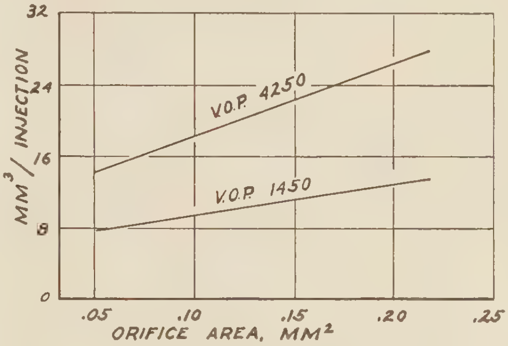

Fig. 8 Minimum Regular Quantity of Injection Increases With Orifice Area

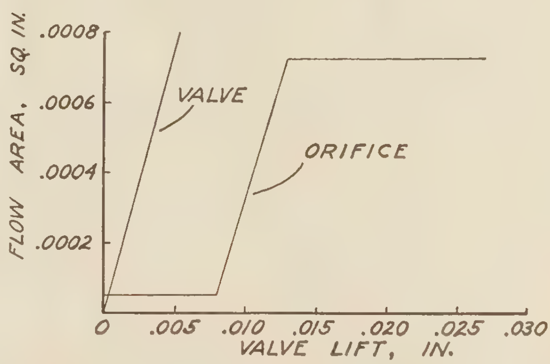

Fig. 9 Valve and Orifice Areas at Various Lifts; Pintle Nozzle

keep the orifice area small for this reason if the minimum lies in or near the operating range of quantity of the engine.

These orifice-area limitations are largely overcome in the variable-area-orifice closed nozzle. Fig. 9 shows the valve-area-orifice-area relationship in a so-called "pintle" nozzle. In this particular design, the valve area is larger than the orifice area at lifts above 0.0005 in., whereas, if the orifice area were fixed at its maximum, this would be true only at lifts above 0.004 in. Hence, valve throttling is tremendously reduced with such a design. Such a nozzle also possesses an inherent damping action against valve fluctuation at low delivery rates since, as the valve tends to close, the orifice area grows smaller and the instantaneous rate of injection decreases. This tends to keep up the *EIP* and keep the valve open. A variable-area-orifice nozzle with a high differential ratio can be designed to give a continuous injection over a wide speed range quite impossible with a nozzle having a fixed orifice equal to the maximum area of the former.

A comparison of the atomizations of two such nozzles can be easily made on a hand pump. Let both nozzles have the same *VOP* and *VCP*, and let the plain-hole area be equal to the maximum area of the variable orifice. The pressure should be slowly raised and the sprays noted in strong crosslighting against a dark background, as in Fig. 10. Many more large drops, far ahead of

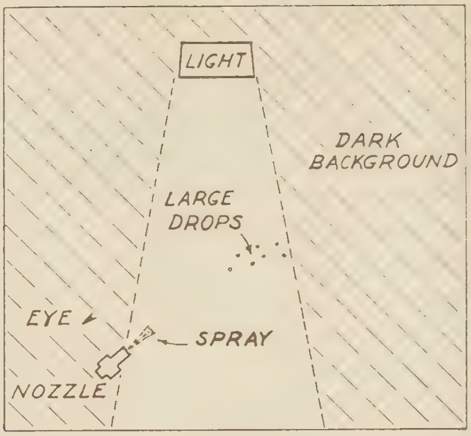

Fig. 10 Showing Correct Lighting for Visual Detection of Poor Atomization

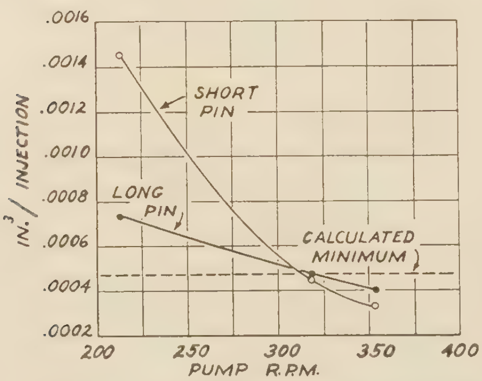

Fig. 12 Effect of Changing Orifice-Area-Lift Relationship on Minimum Regular Quantity of Injection (*VOP* 1700 psi; *VCP* 1150 psi.)

the spray tip, will be seen with the plain-hole orifice. The larger the orifices, the greater the differences will be. The same test, of course, may be applied in other cases to detect rather wide differences in the amount of low-pressure injection.

The ability of a variable-area-orifice type to reduce much of the low-pressure injection, or dribble, results in more of the jet shooting clear of the face of the nozzle. When connected to a pump running at slow speeds, a plain-hole closed nozzle will usually "wet its face" more than a variable-orifice type of the same maximum area. This is thought to be the reason why the pintle type is freer of carbon rather than the commonly accepted reason of mechanical-wiping action. One bit of supporting evidence for this theory was a series of tests run on the two variable-area-orifice designs of Fig. 11; nozzle (*a*) having wiping action and nozzle (*b*) none. Both had the same area-lift relationship and the same *VOP* and *VCP*. After a rather severe carbonization test, the carbon was as indicated, and the same in both. Other carbonizing runs confirmed the equal tendency of both designs toward carbonization. Another bit of evidence is that lowering the *VOP* of a pintle nozzle increases the amount of carbonization. In many engines, it is in fact this deposit which determines the minimum *VOP* required.

The minimum regular quantity for a nozzle of the design of Fig. 11 (*b*) is shown in Fig. 12. The variable areas were the same in both curves except that, in the case of the long pin, the stem had to lift 0.006 in. higher before the initial area changed to the maximum area. This tended to keep the orifice area small and so produced the more favorable curve. The dashed curve shows the minimum quantity calculated on the basis of compressibility. The variable-area design, by providing a small orifice when the duration (and quantity) is small, and by permitting the use of a higher differential ratio without valve throttling, makes possible the injection by a closed nozzle of smaller minimum quantities than otherwise.

Comparison of Throttling and Nonthrottling Nozzles

One of the most interesting developments of the variable-area design is the so-called "throttling" type. This term refers to

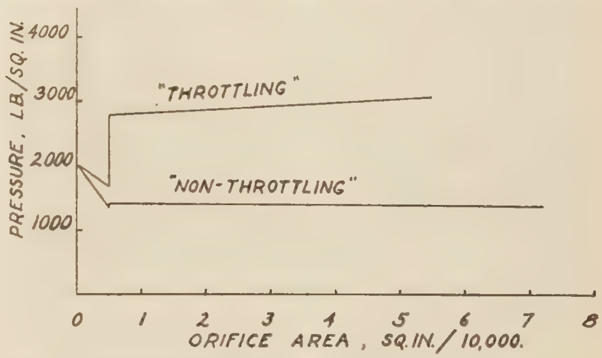

Fig. 13 Pipe-Pressure-Orifice-Area Curves for Throttling and Nonthrottling Pintle Nozzles, Both Set at 2000-Psi *VOP*

the slow rate of increase of area with pressure, and not to throttling in the usual hydraulic sense. The area-pressure relationships in a "throttling" and "nonthrottling" type, both of commercial design, are shown in Fig. 13. These curves have been calculated on the following assumptions:

1 The *VOP* is 2000 psi in each case.

2 The *EIP* is the full amount of the pipe pressure when the valve area equals the orifice area. In both cases this occurs when the areas are 0.00005 sq in.

3 Loss of pipe pressure at smaller valve areas varies indirectly with that area.

4 The change in effective stem area due to change in orifice area is negligible.

5 The effects of stem displacement and inertia can be neglected.

In these two designs the *VCP* of the nonthrottling type is then 1350 psi and that of the throttling type 1650 psi. This higher differential ratio, in conjunction with a higher spring rate and a more gradual shape of annulus pin, results in a much higher pressure being required in the throttling type to increase the orifice area to its maximum.

The advantage of such a design lies in the lower initial rate of injection, desirable in some combustion chambers.

Fig. 14 shows a comparison of the rate curves of a throttling and nonthrottling nozzle. Both nozzles had the same differ-

ential ratio, the orifices and springs alone making the differences. Test conditions were identical except that the pump timing was shifted 1 deg to give the same start of injection, and the quantity control was reset to give 53 mm³ per injection in each case.

The disadvantage, hydraulically, of the variable-area-orifice nozzle is its low coefficient of discharge. Reviewing this matter briefly, there are three jet coefficients to be considered. In Fig. 15, the ratio of the minimum area A_j of the jet to the orifice area is called the coefficient of contraction c_c. The jet velocity V_j in this section, divided by that given by the Torricelli law, gives the coefficient of velocity c_v. The coefficient of discharge is the product of these two $c_d = c_c \times c_v$. Term c_v is of importance since a low value means poor atomization and requires an increase in *EIP* to offset its effect, while a low c_c merely requires a larger orifice. Because of experimental difficulties, little has been done in fuel-injection research in measuring c_v. One of the few reporting such results is Schweitzer (6) who determined the mean

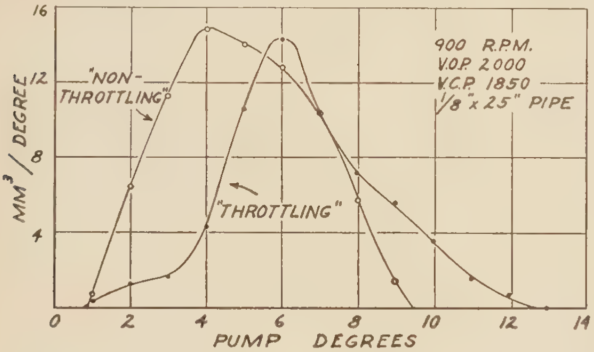

Fig. 14 Rate of Discharge of Throttling and Nonthrottling Nozzles
(Start of injection is at left.)

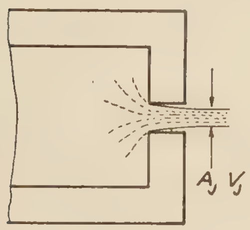

Fig. 15 Jet From Orifice, Showing Contraction

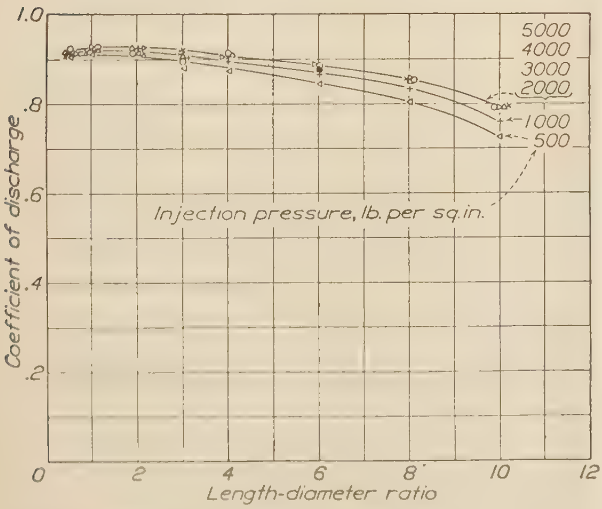

Fig. 16 Effect of L/D Ratio on Coefficient of Discharge

spray velocity at the nozzle. Values of practically unity at 1000-psi pipe pressure down to 0.94 at 8000 psi were found.

It is quite possible to draw certain conclusions from the more exhaustive work done on c_d regarding c_v. For example, Fig. 16 from Gelalles (7) shows the effect of L/D ratio on c_d at several pressures. Since it is known in other hydraulic work that increasing the L/D ratio increases the friction and tends to reduce c_v, but tends to increase c_c, the evidence is that in this test c_v was falling at least as fast as c_d. In other words, long orifices reduce the jet velocity at least as much and probably more than the coefficient falls in Fig. 16.

In annular orifices, the L/D ratio is unfavorable. This is because the dimension D is the thickness of the annulus and not the total annulus diameter. In some commercial designs, this annulus thickness is a minimum, when the valve is seated, of only 0.0004 in., while the length is 0.0208 in., giving an L/D ratio maximum of 52:1. In the variable-area-orifice design of Fig. 4, in which the annulus is the valve itself, the ratio approaches infinity as the valve seats. In any case, the ratio becomes more favorable as the stem lifts and the orifice area increases, for the simple reason that every annulus must have a finite length. Table 1 shows the effect of orifice area on c_d in a variable-area-orifice nozzle. The low values of c_d at small lifts clearly show the effect of fluid friction in reducing the jet velocity. There is thus a minimum orifice area which may be advantageously used in the variable-orifice nozzle, the practical lesson being to make annular clearances as large as possible by keeping the annular diameters as small as possible The over-all effect, however, has generally been greatly to the advantage of the variable-area-orifice closed nozzle, wherever a wide range of speeds has been involved, and this largely accounts for the popularity of such designs in today's flexible Diesels.

TABLE 1 EFFECT OF ANNULAR-ORIFICE AREA ON COEFFICIENT OF DISCHARGE

Lift of stem, in.	Annulus area, sq in.	c_d
0.006	0.00024	0.26
0.010	0.00033	0.54
0.016	0.00046	0.70
0.018 (max)	0.00051	0.74

Variation in Shrinking and Swelling of Wood

By A. J. STAMM[1] and W. K. LOUGHBOROUGH,[2] MADISON, WIS.

The purpose of this paper is to point out that while the forces that cause wood to shrink and swell are chemical in nature, the factors which influence the degree of external dimension change are largely physical or mechanical. Orientation of the structural units, specific gravity or porosity of the wood, and the stresses set up by moisture gradients determine the change in external dimensions as the wood loses or gains moisture. Water-soluble extractives, because of their bulking effect, reduce the shrinkage of wood.

THE shrinking or swelling of the substance of which the cell walls of wood are composed is dependent upon the chemical nature of the wood. The extent to which this shrinking and swelling is transmitted to the external dimensions of the wood is also dependent upon (*a*) the orientation of the structural units, (*b*) the nature and extent of the gross capillary structure, and (*c*) the stresses set up in the wood due to moisture-content gradients or external forces.

Effect of Chemical Composition

The shrinking or swelling of the substance of which the cell walls of the wood are composed, except for a slight adsorption-compression correction (1, 2),[3] is equal to the volume of water lost or gained up to a saturation value known as the fiber-saturation point (3, 4). Values for the fiber-saturation point obtained by a number of different methods vary from about 27 to 33 per cent at room temperature (3). The shrinking and swelling of the wood substance of different species should thus not vary by more than about 20 per cent.

Wood is made up of cellulose, together with other carbohydrate materials, lignin, and extractives. Moisture content - relative vapor pressure data indicate that the holocellulose (the hemicellulose and cellulose in the wood) and lignin are about equally hygroscopic, that is, they have about equal fiber-saturation points (5). The stable cellulose portion of the holocellulose (the alpha cellulose) is somewhat less hygroscopic than the hemicellulose portion. This might account for the tendency for hardwoods (woods from broad-leaved deciduous trees) to have slightly higher fiber-saturation points than softwoods (woods from needle-bearing coniferous trees) as the former have somewhat higher hemicellulose contents than the latter.

The extractives of wood, which are not part of the fibrous structure but are merely infiltrated into the structure, may be divided into two groups: (*a*) Extractives which are soluble only in organic solvents and are deposited only in the coarser microscopically visible capillary structure; and (*b*) extractives which are soluble in water and, as a consequence, are distributed throughout both the free water in the coarse capillary structure and the bound water within the cell walls. The former have no effect upon the shrinking and swelling of wood, but they do affect the specific gravity of wood and, as a consequence, will affect the shrinkage - specific gravity relationship. The water-soluble extractives, however, have a definite effect upon the shrinking and swelling of the cell-wall structure, and, therefore, also affect the shrinking and swelling as transmitted to the external dimensions.

It has been demonstrated by Stamm (6) that water-soluble salts enter the bound water within the cell-wall structure and attain a concentration virtually equal to the concentration in the coarse capillary structure. When wood is dried, free water is first removed from the coarse capillary structure. The salt concentration thus increases in the coarse capillary structure and, as a consequence, salt diffuses into the bound water where the concentration is less. When the drying process is sufficiently slow and the solubility of the salt is sufficiently high so that all the salt within the wood structure will dissolve in the bound water, practically all the salt is finally transferred to the cell-wall structure when drying to the fiber-saturation point. During this process either an equal volume of water or a somewhat smaller volume of water than the volume of the salt taken up is displaced from the cell-wall structure (6, 7). The wood substance thus either retains its water-swollen dimensions or swells slightly, depending upon the nature of the salt (4, 6, 7). When the drying of the wood is continued to the oven-dry condition, the shrinkage is reduced below that which would have taken place if the wood contained only water by an amount equal to the volume of the salt within the cell-wall structure, as the salt is not evaporated. Hence, the reduction in shrinkage is equal to the volume of salt entrapped in the cell wall. This volume can be calculated from the partial specific volume of the salt in the solution when only enough solution is present to fill the transient cell-wall capillary structure (6).

Measurements were made on a series of thin cross sections of green redwood in order to determine the effect of the extractives on the shrinkage. Part of the sections were extracted for 2 weeks in frequently changed water at 60 C. At the end of that time no color appeared in the water after 1 day of soaking. The remainder of the sections were held in a sealed jar at the same temperature. The water-soluble extractive content of the sections was 14.5 per cent and the specific gravity of the extractives was about 1.5. The sections were then dried for 3 days at 90 per cent relative humidity, 2 days at 65 per cent, and 2 days at 30 per cent relative humidity, followed by oven drying for 1 day. The average shrinkage of area, which is practically equal to the volumetric shrinkage, of the extracted sections was 7.7 per cent and of the unextracted sections 6.2 per cent. The average dry weight - green volume specific gravity of the former sections was 0.313 and of the latter 0.353. The presence of the extractives reduced the shrinkage by 19.5 per cent. If the fiber-saturation point of the wood on a volume of water per unit weight of wood is 0.27, then $0.27 \times 0.195 = 0.0525$, which represents the volume of extractives within the cell-wall structure per unit weight of wood necessary to give the experimental reduction in shrinkage.

Contributed by the Wood Industries Division and presented at the Fall Meeting, Louisville, Ky., October 12–15, 1941, of The American Society of Mechanical Engineers.

This is equivalent to an extractive content of 7.9 per cent of the weight of the dry wood, which is slightly more than one half of the actual amount of extractives present. The fact that only part of the extractive content is effective in reducing the shrinkage is quite logical, as it can be shown from microscopical observation that an appreciable part of the extractives is deposited within the coarse capillary structure, where it can have no effect upon shrinkage.

The data thus indicate that the shrinkage of redwood, which contains an appreciable amount of water-soluble extractives, is considerably lower than it would be if no extractives were present. It is largely for this reason that redwood and woods containing large amounts of water-soluble extractives shrink less than would be predicted on the basis of the shrinkage-specific gravity relationship to be considered later.

Fig. 1 Photomicrograph of Isolated Wood Fiber
(This shows outer fibril wrapping at right angles to fiber direction intact over part of fiber length, and ballooning of fiber where it has been removed; reference 9.)

Effect of Structural Orientation

The differences in the shrinking and swelling of wood in the different structural directions are due to the highly organized orientation of the structural parts. This orientation also has a very definite effect upon the proportion of the dimension changes which are transmitted to the external dimensions.

The cell walls of wood are believed to be made up primarily of bundles of long threadlike submicroscopic molecules of cellulose, in which zones along the length of the threads are bunched into highly oriented bundles, with zones in between in which the orientation is less perfect. Molecular threads emerging from a single bundle may enter either of several adjacent bundles (8). The less perfectly oriented zones of cellulose threads are believed to be incrusted with hemicelluloses and probably some lignin. The microscopically visible fibrils into which the cell walls can be broken down are made up of large multiples of these submicroscopic threads. Most of the fibrils are oriented at only a slight angle to the length direction of the fibers (9). There is, however, an outer wrapping composed of fibrils which are oriented practically at right angles to the fibers (9). Fig. 1 shows a highly magnified photomicrograph of an isolated wood fiber taken from a report by Ritter (9) in which the outer fibril wrapping is clearly shown on part of the fiber. The ballooning of the fiber in the zone where the fibril wrapping has been removed will be considered later.

X-ray evidence indicates that the adsorbed water is taken up between the highly oriented bundles of threadlike molecules and within the zones of less perfect orientation to add its volume to the volume of the cell walls (10, 11). The dispersing of the structural units thus takes place almost entirely at right angles to the direction of the orientation of the threadlike units. That only a limited amount of water can be taken up within the cell wall is apparently due to the fact that the threadlike molecules which pass from one highly oriented bundle to another do so in such a random way as to tie all of the bundles together through chemical bonds.

Normal woods shrink and swell only about 1 to 2 per cent as much in the fiber direction as across the fibers. This is readily explainable on the basis of the fiber structure just given. The fact that the longitudinal shrinking and swelling is as large as it is, is due to deviations from a linear orientation of the structural units thus causing a slight component of the transverse-dimension changes to occur in the longitudinal direction.

It has been shown by X-ray means that the fibril orientation in compression wood deviates more than normal from the fiber direction (12). As a consequence, compression wood shrinks and swells more than normal woods in the fiber direction (13).

The cellulose fibers of wood are cemented together by a continuous middle lamella of lignin and hemicellulose. The shrinking and swelling of the middle lamella must conform largely to that of the fibers which it surrounds. If this were not the case, there would be evidence of the middle lamella breaking away from the cell wall as a result of shrinking or swelling. The middle lamella evidently possesses enough elasticity, due to molecular rearrangement under stress, to account for this as well as the flexibility of wood.

The shrinking and swelling of wood is from 1.5 to 3.5 times as great in the tangential direction (the direction of the annual rings) as in the radial direction (the direction of a plane through the diameter of the tree) (14). This was formerly believed to be due to ray cells restraining the dimension changes of the wood in the direction of their length, as a result of the assumed orientation of the threadlike units of which the ray cells are composed being in the length direction of the ray cells. It has been recently shown by Ritter and Mitchell (15), however, that the ray cells are made up almost entirely of structural units oriented in the lengthwise direction of the tree. Hence there can be no appreciable restraining action on the shrinking and swelling of wood in the radial direction by the ray cells. Ritter and Mitchell (15) have explained the difference between tangential and radial shrinking and swelling on the basis of the pits which are concentrated on the radial faces of the fibers. The structural units of the radial faces, in passing around the pits, are necessarily less perfectly oriented than on the tangential faces where there are few pits. Consequently, there is less of a transverse shrinking-and-swelling component in the radial than in the tangential direction. Frey-Wyssling (16) has recently come to a similar conclusion.

Moisture Content - Shrinkage Relationships

The external shrinkage of practically all the softwoods and many of the hardwoods, in any one of the structural directions or combinations of directions, is approximately proportional to the moisture lost from the fiber-saturation point to the dry condition. Fig. 2 gives a typical set of curves for the volumetric shrinkage of loblolly pine boards ($8^1/_2 \times 5^1/_2 \times {}^7/_8$ in.) of different specific gravity, which illustrates this relationship (17). There is a tendency for the lines to have a slightly concave curvature toward the moisture-content axis. This can be accounted for on the basis of the adsorption compression of the bound water (1, 2). There is also a tendency for the lines to show a reverse curvature at moisture-content values just below the fiber-saturation point. This is in large part due to the fact that, in drying specimens of any appreciable dimensions, the outer part of the wood falls below the fiber-saturation point and tends to shrink,

while the average moisture content is still above the fiber-saturation point.

In the case of the normal woods, such as the loblolly pine, the break in the approximately linear relationship can be made to occur much nearer to the fiber-saturation point by very slowly drying thin cross sections of the wood, so as to minimize moisture gradients and resultant drying stresses (14). In the case of some of the hardwoods, notably Southern swamp oak, Fig. 3, the Australian eucalyptus species (14), and beech (18), there is a much more marked tendency for an appreciable shrinkage to occur above the normal fiber-saturation point. This type of shrinkage curve will be considered in more detail later.

When the external volumetric-shrinkage measurements are made on thin transverse wood sections less than 1 fiber length in

thickness, which have been previously dried and resoaked, the extrapolation of the linear portion of the curve back to zero shrinkage gives moisture-content intercepts practically equal to the fiber-saturation point of the wood as obtained by other methods (3). The same is roughly true for the extrapolation of the tangential- and radial-shrinkage curves. The tangential- and radial-shrinkage curves, however, often give slightly different intercepts, the tangential usually being slightly higher than the radial (14). The deviation in intercepts can be explained either on the basis of the greater tangential than radial shrinkage causing a greater intensity of tangential than radial stresses and, consequently, a greater deviation from the theoretical stress-free shrinkage; or on the basis of a differential relief of stresses which exist in the green wood. The presence of such stresses is indicated by the fact that Koehler (19) found green wood to increase slightly in tangential dimensions and decrease in radial dimensions on boiling in water.

The practically linear moisture content - shrinkage relationships would be expected to hold for wood substance, as the volume change would then be entirely due to the removal of bound water and should, in fact, be equal to the volume of bound water removed. The fact that the relationship holds, in general, for the externally manifested dimension changes of wood is due to the nature of the internal-dimension changes which will be considered in the next section.

Effect of Capillary Structure

Wood varies in specific gravity from about 0.25 to 1. The specific gravity of wood substance is practically constant for all species, the average value as determined in helium being 1.46 (2, 20). This means that the internal voids of wood, which contain either water or air, amount to 83 to 31 per cent of the overall volume. The question thus arises as to how this large void volume affects the shrinking and swelling of wood as transmitted to the external dimensions.

If wood were made up of an unoriented material like a gelatin jelly, the presence of capillary voids would not affect the shrinking and swelling as transmitted to the external dimensions, if the drying or soaking conditions were such as to avoid undue moisture-content gradients and resultant stresses. For example, a thin disk of gelatin jelly with a hole in the center will show the same external-dimension changes on shrinking or swelling as if no hole were present. This is due to the fact that the hole changes in dimensions by the same amount as the disk cut from the hole. If wood acted in a similar manner, the shrinking and swelling of wood would not vary with changes in specific gravity. The shrinking and swelling of wood, in general, increases with an increase in the specific gravity, Fig. 2. This can be accounted for on the basis of the fiber structure. If the cross section of a dry wood fiber is observed under the microscope, it appears like the gelatin disk with a hole through the middle. When a drop of water is placed on the slide near the fiber cross section, it swells at first in a similar manner to the gelatin disk. The diameter of the fiber cavity, as well as the external dimensions, increases. When the external swelling has progressed to the point where the outer wrappings at right angles to the fiber axis are taut, further swelling is forced to be internal and the fiber cavities then decrease in size. On the average, the fiber cavities change but slightly in size for most of the species between the swollen and the dry condition.

The restriction of the external swelling of an isolated wood fiber by the outer fibril wrapping is illustrated in Fig. 1. The lower part of the fiber, from which the outer wrapping has been removed, swells entirely in the external direction. The presence of the wrapper, however, forces a large part of the swelling to occur into the fiber cavity.

Schwalbe and Beiser (21) found, from an analysis of their data for the swelling of spruce, that the fiber-cavity dimensions are practically unchanged when assuming a fiber-saturation point of their wood of 30 per cent. Beiser (22) also has shown from microscopical studies of the cross sections of spruce and beech that the change in size of the fiber cavities resulting from shrink-

ing and swelling of the wood is small. He found that the fiber cavities of springwood increase in diameter slightly or do not change at all upon swelling of the wood, while the fiber cavities of summerwood actually decrease slightly in size. Stamm (23) has also shown, from data on the permeability of the fiber cavities to air of different relative vapor pressures, that the size of the fiber cavities of thin transverse sections of Western white pine and Western hemlock remain practically constant under different degrees of swelling.

The approximate constancy of the size of the fiber cavities between the swollen and the dry condition indicates that part of

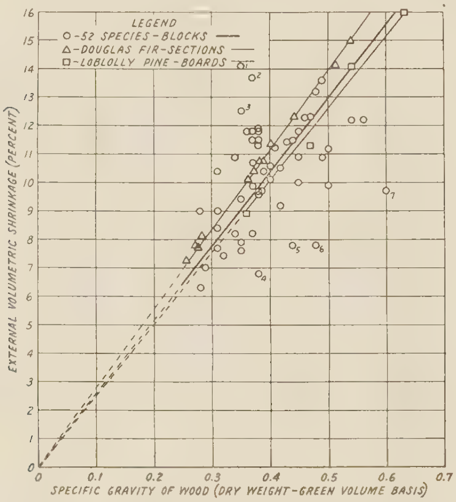

Fig. 4 Average External Volumetric Shrinkage of 2 × 2 × 6-In. Specimens for Each of 52 Different Species of Softwoods From Green to Oven-Dry Condition, Plotted Against Average Dry Weight - Green Volume Specific Gravity

(Each point represents average of a number of specimens from 4 to 30 different trees; reference (24). Numbered points, which show maximum deviation from the relationship, are for 1 fir, Pacific silver, *Abies amabilis;* 2 spruce, white, *Picea glauca;* 3 fir, noble, *Abies nobilis;* 4 redwood, virgin, *Sequoia sempervirens;* 5 red cedar, eastern, *Juniperus virginiana;* 6 juniper, alligator, *Juniperus pachyphlaea;* 7 yew, Pacific, *Taxus brevifolia.* Similar shrinkage data for thin tangential sections of Douglas fir containing different proportions of springwood and summerwood and for average, maximum, and minimum specific gravity of 50 loblolly pine sapwood boards are also plotted.)

the dimension change occurs internally. This is fortunate for the wood user. If the structure were similar to that of the gelatin jelly, the shrinking and swelling of wood as manifested by external-dimension changes would be several times as great as it actually is.

Stamm (4) has shown that the external volumetric shrinkage of thin tangential sections of Douglas fir, containing different proportions of springwood and of summerwood, which were cut from a single specimen, increase linearly with an increase in the specific gravity of the wood, and that extrapolation of this linear relationship to zero specific gravity gives zero shrinkage, as is shown in Fig. 4. A similar linear relationship is shown for the loblolly pine boards of Fig 2. Other species give similar linear relationships but, in a number of cases, the moisture content-shrinkage regression lines of individual specimens deviate considerably from the mean line of the species.

This same relationship holds in a general way between the average external volumetric shrinkage and average specific gravity of a large number of species of both softwoods and hardwoods, as is shown in Figs. 4 and 5. These data of Markwardt and Wilson (24) are for 2 × 2 × 6-in. specimens of 52 different softwood species, Fig. 4, and of 106 different hardwood species, Fig. 5. Each point represents the average value for a number of specimens taken from 4 to 30 different trees. The slopes of the heavy lines give the mean ratios of the external volumetric shrinkage to the specific gravity for all the data. The mean ratio of the percentage external volumetric shrinkage to the specific gravity for the softwoods is 26 and for the hardwoods is 27. In the case of the softwoods, 50 per cent of the species show a deviation of less than 10 per cent from the mean value and 75 per cent of the species show a deviation of less than 19 per cent from the mean value. In the case of the hardwoods, 50 per cent of the species show a deviation of less than 11 per cent from the mean value, and 75 per cent of the species show a deviation of less than 22 per cent from the mean value. Greenhill (25) gives data for the shrinkage versus specific gravity of 170 different Australian species before reconditioning. The mean ratio of the percentage external volumetric shrinkage to specific gravity is about 27, in excellent agreement with the foregoing values. The deviations from the mean value are, however, somewhat greater in the case of the Australian woods, 50 per cent of the species showing a deviation of less than 21 per cent from the mean value and 75 per cent of the species showing a deviation of less than 33 per cent from the mean value.

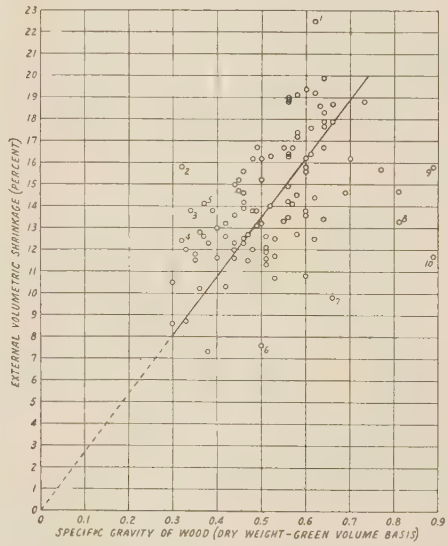

Fig. 5 Average External Volumetric Shrinkage of 2 × 2 × 6-In. Specimens for Each of 106 Different Species of Hardwoods From the Green to the Oven-Dry Condition, Plotted Against Average Dry Weight - Green Volume Specific Gravity

It is of interest that the mean percentage external volumetric shrinkage - specific gravity ratio is practically equal to the average fiber-saturation point of wood, expressed in terms of the volume of water held per 100 g of dry wood (4). Accordingly, the external volumetric shrinkage, S (in per cent), is, on the average, approximately equal to the dry weight - green volume specific gravity of the wood ρ, times the fiber-saturation point f, on a volume of water per unit weight of dry-wood basis (in per cent), thus

$$S = \rho f \longleftrightarrow \left(100\,\frac{l^3}{l^3} = \frac{w}{l^3} \times 100\,\frac{l^3}{w}\right)$$

The equation in parentheses, where l is a linear dimension and w is the weight, shows that the relationship is dimensionally sound.

When the proportionality constant f has a mean value equal to the fiber-saturation point on a volume-of-water basis, the fiber cavities of wood will not change in size when the wood shrinks and swells. This is further confirmation of the findings previously given that the fiber cavities of most woods tend to remain constant in size.

There are a few species, however, which are numbered and listed in Figs. 4 and 5, which shrink either considerably more or less than is compatible with the f value, which corresponds to constant fiber-cavity dimensions. It is of interest that the species having abnormally low shrinkage values are, in general, species which are rather high in water-soluble extractives. It has already been shown that the presence of extractives in redwood is largely if not entirely responsible for the low shrinkage. Removal of the water-soluble extractives shifted the f value for

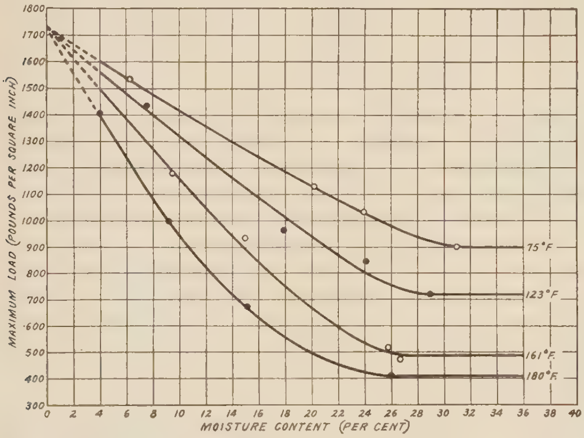

FIG. 6 RELATIONSHIP BETWEEN MAXIMUM LOAD IN TENSION PERPENDICULAR TO GRAIN AND MOISTURE CONTENT OF BEECH AT FOUR DIFFERENT TEMPERATURES

the specimens of redwood tested from the abnormally low value of 18 per cent to the practically normal value of 25 per cent.

EFFECT OF STRESSES

Deviations from the general shrinkage relationship, other than those due to extractives, are due to changes in the fiber-cavity dimensions. These changes result from externally imposed stresses or stresses resulting from moisture gradients, induced by either a process of moisture loss or moisture regain.

An extreme case in which the externally manifested shrinking and swelling can be shifted to internal-dimension changes has been demonstrated by Tiemann (26). A dry block of wood is clamped in a mechanical device so that its external dimensions cannot change. It is then placed in a water-saturated atmosphere or in water and allowed to come to equilibrium. When removed from the clamp and dried the external dimensional shrinkage is practically the same as if the block had previously swollen normally. If the block is again clamped in the mechanical device and allowed to absorb water, followed by drying, the block shrinks to yet smaller external dimensions than after the first drying. After ten such cycles Tiemann has shown that the volume of a block of wood can be reduced to about two thirds of its original value. Perkitny (27) has similarly shown that mechanical restraint in a single direction increases the shrinking and swelling in the other directions. In the case of plywood mechanical restraint practically eliminates both swelling and shrinking in the sheet directions. The actual swelling and shrinking is not reduced, however, but merely shifted to the thickness direction and internally into the fiber cavities.

It is thus evident that wood which is subjected to abnormally high compressive forces while drying will shrink more in external dimensions than normal and the fiber cavities will be reduced in size. Conversely, wood which is subjected to abnormally high tension forces while drying will shrink less in external dimensions than normal and the fiber cavities will be increased in size.

The effects due to drying stresses are somewhat more complicated than those due to externally applied forces, because both

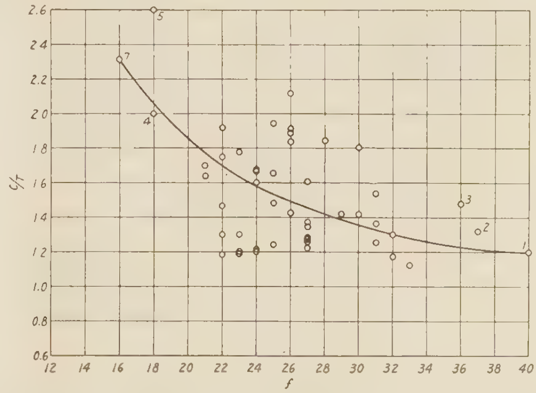

FIG. 7 VARIATIONS OF AVERAGE EXTERNAL VOLUMETRIC SHRINKAGE (IN PER CENT)—SPECIFIC GRAVITY (DRY WEIGHT - GREEN VOLUME) RATIO f, WITH RATIO OF AVERAGE COMPRESSIVE TO AVERAGE TENSILE STRENGTH PERPENDICULAR TO GRAIN FOR GREEN WOOD C/T, OF EACH OF 49 DIFFERENT SPECIES OF SOFTWOODS

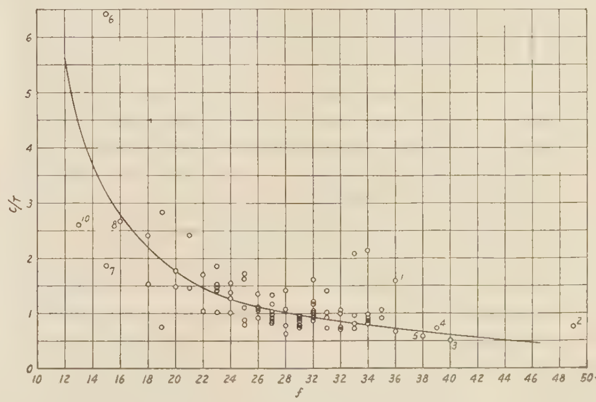

FIG. 8 VARIATION OF AVERAGE EXTERNAL VOLUMETRIC SHRINKAGE (IN PER CENT)—SPECIFIC GRAVITY (DRY WEIGHT - GREEN VOLUME) RATIO f, WITH RATIO OF AVERAGE COMPRESSIVE TO AVERAGE TENSILE STRENGTH PERPENDICULAR TO GRAIN FOR GREEN WOOD C/T, OF EACH OF 89 DIFFERENT SPECIES OF HARDWOODS
(Numbered species are the same as in Fig. 5.)

tension and compression stresses are set up in different parts of the wood at the same time. These stresses are always in balance because of the fact that they are autoapplied and self-contained. The neutral axis is constantly shifting as the wood dries. The surface fibers go from maximum tension in the early stages of drying to compression when the process is complete. Conversely, the central fibers are at first squeezed and in the final stages of drying they are stretched. Not only do the stresses vary as drying progresses, but also the resistance to the stresses, due to the fact that dry wood is stronger than wet wood, Fig. 6.

When a green board is exposed to a drying atmosphere the surface fibers soon attain a moisture content which is well below the fiber-saturation point. Thus, a moisture gradient is es-

tablished. As drying continues, the moisture distribution changes constantly. Successively lamina by lamina the number of fibers which have been dried below their fiber-saturation point increases and the number which are not dry enough to shrink decreases. As the normal shrinkage tendency is directly proportional to the moisture lost below the fiber-saturation point, there is a constantly shifting stress pattern which follows the changing moisture distribution.

If, as is usually the case, the tension stress set up in the surface lamina exceeds the elastic limit in tension perpendicular to the grain, the surface lamina becomes set in tension. If the tensile strength at maximum load is exceeded the piece fails, creating a surface check. If, on the other hand, the surface stresses are not relieved by face checking of the wood, they exert a compression upon the inner laminae which have not dried. If this compression exceeds the compressive strength of the wood, the fiber walls will collapse into the fiber cavities.

Collapse, occurring in the early stages of drying, has also been attributed by some investigators (14, 25, 28) to a liquid tension set up in the fiber cavities which are completely full of water. This tension results from the evaporation of water from the fiber cavities through pit membrane openings which are so small that they reduce the relative vapor pressure of the water by an amount such that the vapor tension exceeds the compressive strength of the cell walls. Such a tension can be set up only when the fiber cavities are completely full of water, since any contained air bubble, which has a greater diameter than the largest opening through which evaporation occurs, will expand under the tension and, as a consequence, relieve the stress on the cell wall. These conditions for liquid-tension collapse may be met by randomly distributed fibers in the case of some species. In practice, however, the collapsed fibers are not randomly distributed throughout the wood but are located in the central zone which is under compression. For this reason, and others which will be discussed later, it appears to the authors that collapse is more generally due to compression stresses set up during the drying process than to a liquid tension.

When wood is dried under controlled conditions, moisture-content gradients near the surface are not permitted to become sufficiently steep to cause face checking. If the wood is equally strong in compression and in tension perpendicular to the grain, the wood will normally not collapse. Under these conditions, the tension set up in the surface fibers will tend to keep the fibers stretched. As drying progresses, a zone a little farther into the wood will dry below the fiber-saturation point and change from a zone under compression to one under tension. Meanwhile, the outer zone under the influence of the tension stress becomes set in tension, that is, retains its dimensions, even though the tension stresses are relieved. Each lamina of the wood in to the center will successively be subject to a tension stress. Naturally, under these conditions, the shrinkage of the wood will be less than it would have been if drying stresses had been absent.

If, on the other hand, the compressive strength of the wood perpendicular to the grain is considerably less than the corresponding tensile strength, then a drying gradient which will avoid face checking of the wood may be sufficiently great to cause collapse within the inner part of the wood. The zone in which collapse occurs will collapse before that zone has fallen below the fiber-saturation point since any shrinkage in the zone will naturally relieve the compressive stress.

From this it appears that woods which have a high compressive strength relative to the tensile strength perpendicular to the grain will tend to shrink less than normal, whereas, woods which have a low compressive strength relative to the tensile strength perpendicular to the grain will tend to shrink more than normal. That this is the case is illustrated by the data of Figs. 7 and 8, in which the shrinkage - specific gravity ratio values of Figs. 4 and 5 are plotted against the ratio of the compressive to the tensile strength perpendicular to the grain for the green wood. A few of the species shown in Figs. 4 and 5 had to be omitted in Figs. 7 and 8 because of the lack of tensile-strength data, thus accounting for the fewer points. Although there is considerable spread among the points, the trend is obvious.

It should be pointed out that the strength values used (24) are those obtained for mechanical purposes and deviate somewhat from the values which should be used here. The compressive-strength values of Markwardt and Wilson include a shear factor around the edges of the plate causing the compression, so that they will be slightly higher than the desired compression values. The tension values, on the other hand, are probably a little low, due to a slight experimentally unavoidable bending moment. The ratios of compressive to tensile strength may thus be somewhat high but their relative values should be approximately correct.

In order to analyze comprehensively the effects of stresses on the shrinkage of wood, it would be necessary to know both the tensile and compressive strengths perpendicular to the grain both at different temperatures and for different moisture contents. A valuable start has been made by Greenhill (29) in obtaining such data. His investigation was confined entirely to the tensile-strength properties of beech perpendicular to the grain. The data show a decrease in the maximum load, Fig. 6, the load at elastic limit, and the modulus of elasticity both with an increase in temperature and an increase in moisture content. He also obtained a decrease in unit deformation at maximum load with a decrease in temperature for temperatures below 120 F, which seems to correspond to the temperature of maximum deformation.

It is highly probable that for some woods the decrease in compressive strength perpendicular to the grain with increases in temperature and moisture content will parallel the tensile-strength values, whereas in other cases the decrease in the compressive-strength values may appreciably exceed the decrease in tensile-strength values. This is indicated by the fact that white-pine specimens dried at winter air-drying temperatures and also at 170 F under several different relative-humidity conditions give practically the same shrinkage, presumably because the ratios of tensile- to compressive-strength values are about equal under the various conditions. White oak, on the other hand, gives a rather large increase in shrinkage with an increase in the drying temperature which indicates that the compressive strength perpendicular to the grain must decrease considerably more rapidly than the corresponding tensile strength as the temperature is raised. This would promote an increase in both forms of collapse with an increase in temperature.

Steaming of wood, after it is partially seasoned, results in a reduced shrinkage on subsequent drying (25, 28). The steaming raises the moisture content and causes swelling of the outer lamina to the point at which the normal drying stresses are reversed. The outer lamina is put under compression and the inner part of the wood under tension. This tension tends to relieve the previous compression of the inner part of the wood, resulting in an expansion of the wood as a whole. When the steamed wood is again dried it is normally subjected to a lower relative humidity than that at which drying was initially started, as the wood is less susceptible to face checking. This rapidly puts the outer lamina again in tension and results in a tension set which brings the center of the wood under further tension as drying progresses. The resultant is the setting up of a tension stress in the center of the wood, both during steaming and subsequent drying. The shrinkage is therefore reduced below the normal for normal wood and still more for wood which is subject

to either a compression collapse or collapse due to a liquid tension.

This method of reducing the shrinkage of wood by reconditioning with steam is extensively used in Australia on species of wood which shrink greatly (25). According to the data of Greenhill (25), the shrinkage of Australian timbers can, on the average, be reduced to about 70 per cent of the normal value by using this steaming process. That is to say, the average shrinkage - specific gravity ratio is reduced from the normal value of 27, as previously mentioned, to 19. Because of the fact that on the average the fiber cavities of the Australian woods did not change in size on normal drying and actually increased in size after reconditioning, the process is, in general, one of creating a tension set in normal wood rather than one of recovering collapsed wood from collapse. Although collapse undoubtedly took place in the case of the woods having abnormally high shrinkage - specific gravity ratios, the reduction in shrinkage by steaming does not indicate that collapse had necessarily taken place.

The peculiar moisture content - shrinkage curve, of Fig. 3, can be explained on the basis of drying stresses. The drying of the outer part of the wood caused a compression stress on the green inner zone which was sufficiently great to result in a collapse of the inner fibers. During the early stages of drying the inner part of the wood offered little resistance to the shrinkage of the surface fibers. The inner fibers, therefore, were squeezed. The over-all shrinkage was made possible by a decrease in the size of the cell cavities in the portion under compression. In due time when the compressed interior fibers began to lose hygroscopic moisture, the shrinkage of these fibers occurred so as to relieve the squeeze, rather than manifesting itself externally in the usual manner. When the elastic limit in compression of the wet fibers has not been exceeded, the cell cavities will gradually attain their original size as shrinking continues. On the other hand, if the elastic limit has been exceeded, the cell cavities will only partially regain their original size.

Regardless of whether the elastic limit has been exceeded or not, the space occupied by the compressed fibers will not become smaller until the compressive force has been neutralized by their shrinkage. This accounts for the relatively flat section of the moisture - shrinkage curve. In the early stages of drying, tension set in the outer zones of the wood developed tardily and only to a minor extent, due to the high relative humidities employed and to the plasticity of the core. For this reason the tension stress was not able to overcome the collapse completely. Normal shrinkage thus occurred during the last stages of drying. This is indicated by the approximate parallelism of the latter part of the shrinkage curve with the theoretical curve for wood of the same specific gravity.

When wood that gives a shrinkage - moisture content curve like that of Fig. 3 is commercially dried, it is subject to honeycombing. This occurs when the core has been stressed in compression beyond its elastic limit when green. Under these conditions, particularly at high temperatures, a high degree of tension set in the outer zone puts the collapsed fibers into tension which can only be relieved as they dry by internal rupture of the structure.

A moisture contents—hrinkage curve with a similar but much less pronounced hump to that in Fig. 3 was obtained by Stevens (18) for the drying of thin cross sections of beech only $^1/_8$ in. in the fiber direction. This indicates that drying stresses are still somewhat effective even in such thin transverse sections.

The size of the wood specimen will affect the shrinkage in so far as the size of the specimen affects drying stresses. Although the use of thin sections of wood cut across the fibers would be expected to minimize drying stresses appreciably, considerable evidence has been accumulated to indicate that these stresses are never completely eliminated. In the case of many woods these stresses are insufficient to affect the shrinkage appreciably. Presumably, these woods are the ones that have approximately equal tensile and compressive strengths perpendicular to the grain.

The shrinkage of $^1/_8$-in. cross sections of the numbered species in Figs. 4 and 5, which showed abnormally low and also abnormally high shrinkage values in larger specimens, continued to be both low and high, indicating that drying stresses were still present. These sections were initially dried at 90 per cent relative humidity. Because of the small size of the sections and the high relative humidity, very little tension set was obtained. Even under these conditions, drying of the tangential faces was not uniform because the edges dried a noticeable amount before the center of the faces. This exerted a dead-load squeeze on the inner zone, which was, naturally, accentuated by relative humidities that minimize tension set. For this reason all the sections shrunk slightly more than the larger blocks. It thus appears that the shrinkage of thin sections will tend to exceed the shrinkage of large specimens, regardless of whether the wood tends to shrink to an abnormally large or small extent. Although tension set can be largely avoided by carefully drying thin cross sections, compression and collapse apparently cannot be avoided.

If the abnormally high shrinkage of the numbered species of Figs. 4 and 5 were primarily due to a liquid-tension collapse, the use of thin transverse sections should have minimized this collapse because most of the fibers were cut across at least once, making it impossible for a liquid tension to be set up within these fiber cavities. It thus appears that the collapse at least of these particular woods is primarily due to a compression stress set up in drying rather than to a liquid tension.

Summary

The shrinking and swelling of wood substance has been shown to depend upon the chemical composition, being chiefly affected by water-soluble extractives which may reduce the shrinkage by 20 per cent or more. The shrinking and swelling, as transmitted to the external dimensions, has been shown to depend also upon (*a*) the orientation of the structural units; (*b*) the nature and extent of the gross capillary structure, and (*c*) the stresses set up in the wood by moisture gradients or external means. The directional shrinking and swelling is shown to be primarily due to structural orientation. There is a tendency for the fiber-cavity size to remain constant when the wood shrinks and swells. This makes the shrinkage tend to be equal to the specific gravity of the wood (dry weight - green volume basis) times the fiber-saturation point of the wood on a volume of water per unit weight of wood basis. Deviations from this relationship are caused by stresses and by water-soluble extractives.

When the compressive strength of the wood perpendicular to the grain is low relative to the tensile strength, the wood tends to collapse under drying stresses, and hence shrinks excessively. When the tensile strength of the wood perpendicular to the grain is low relative to the compressive strength, the wood tends to shrink less than normal under the drying stresses. In the authors' opinion, collapse is more generally due to compressive stresses than to a liquid tension.

Progress in Methods of Edge-Gluing Lumber and Veneers

By H. K. VON MALTITZ,[1] CHICAGO, ILL., AND O. BOLLING,[2] MINNEAPOLIS, MINN.

Boards for lumber cores of plywood, for solid-dimension stock, such as chair seats, solid tops, etc., are still almost universally edge-glued together with conventional cold-setting glues, i.e., animal, vegetable, and casein. Veneers are still widely taped together and, when edge-glued without tape, are generally glued with prespread animal glue. This paper describes new methods and machines[3] for edge-gluing lumber and veneer with waterproof and water-resistant heat-setting adhesives, particularly urea-formaldehyde resin, and points out the advantages gained through adoption of these new methods.

WITHIN the last 5 years, the widespread adoption of synthetic-resin adhesives by the plywood and furniture industries has rendered obsolete the older conventional glues. To date, however, the resin adhesives have been limited chiefly to the gluing together of the laminations or plies of plywood. The older conventional glues are still in general use for edge-gluing of lumber-core stock for lumber-core plywood, solid-dimension stock for chair seats, solid tops, etc., and also for edge-gluing of veneers when tape is not used.

The ideal plywood panel, whether veneer core or lumber core, is one in which all edge joints, as well as the laminations or plies, are welded together with waterproof or water-resistant glue. In like manner, the ideal solid top is one in which the exposed joints are bonded with water- and mold-proof glue. Such edge joints prevent deterioration from exposure to moisture and mold. However, the glues commonly used for edge joints are subject to deterioration from these causes.

For the purpose of this discussion, the edge-gluing methods will be divided into two categories:

1 Lumber: boards or strips from $^1/_4$ in. thickness up.

2 Veneers: rotary-cut, sliced, and sawed sheets from $^1/_4$ in. thickness down.

Edge-Gluing of Lumber With Resin Adhesives

The conventional method of edge-gluing lumber in the United States is by means of clamping the stock in piling clamps or in revolving clamp carriers. The latter method in particular is widely employed throughout all of the wood industries. The most commonly used adhesive for this purpose is animal glue, while vegetable and casein glues are also used for this purpose, but to a lesser extent.

Within recent years, some work has been done in rather isolated instances with the use of urea-formaldehyde resins in clamp carriers. When a fast-acting cold-setting hardener or catalyst is used in the resin-glue mix, the work generally is left in the clamps for approximately 50 min at room temperature (70 to 75 F), or slightly less if the clamp carriers are hooded over and the surrounding air is heated to 110 to 140 F. Preheating the stock will also reduce the setting time. The most rapid gluing is obtained with this method when paint-on hardeners are used, whereby the resin mixed with a slower hardener is applied on one edge and the fast paint-on hardener is applied on the other edge of the pieces to be glued together. However, even with the fastest possible cold-setting resin glue, the clamping time is still approximately 20 to 30 min minimum. Thus, while the use of resin adhesives in the conventional clamping equipment brings about qualitative benefits, no particular advantages are gained from the standpoint of production increase.

Lumber-Core Continuous-Feed Presses

After years of research and thorough testing, a revolutionary new method and machine have been developed for gluing lumber cores and other types of glued-up lumber dimension stock. The purpose of this new machine, known as the lumber-core continuous-feed press, is threefold:

1 Cost reduction.

2 Straight-line production in lumber-core department, eliminating present drying interval necessary to remove glue moisture.

3 Better quality edge-glued joints, through use of waterproof urea-formaldehyde resin glue in place of the usual water-soluble glues. Quality is also enhanced by the prevention of sunken joints in finished veneered-lumber-core panels.

Advantages of New Lumber Edge-Gluing Method

In the conventional lumber-core process, the lumber strips or boards coming from the ripsaw or glue jointer are matched to width. In some instances this is done on a matching saw; in others right at the straight-line ripsaw. Instill other instances, accurate matching to width is not practiced. Instead, the boards for each core are laid up to approximate width only.

The prematched cores are then taken to the piling clamps or clamp carriers and are glued up.

With the lumber-core continuous-feed press, this matching operation is omitted in many cases, because the core or other product is glued up in an endless ribbon of stock and is automatically divided to width by an automatic cross-traveling rip saw, located at the outfeed end of the lumber-core machine. This elimination of the matching operation saves time, material, and labor.

The new lumber-core press further introduces the possibility of greatly increased production with thesame personnel. Ordinarily, one lumber-core machine has the capacity of two or more 40-section clamp carriers.

In some lumber edge-gluing operations, the cores are trimmed to length or are squared up after leaving the clamp carrier and before being veneered. This function can be performed by the lumber-core press in the same operation in which the stock is glued together, by means of end-trim saws, situated at the outfeed end of the machine.

Also to be considered is the fact that, under the conventional core-gluing methods, the cores are usually stick-piled after re-

moval from the clamps, and are then often kiln-dried for 48 hr or more until all glue moisture is dried out. Otherwise sunken joints would later develop. Animal glues, such as used in edge-gluing lumber, are frequently mixed in proportions of 1 part glue to $2^1/_4$ parts water. The liquid glue, therefore, contains approximately 70 per cent water. This glue is spread so that 65 lb or more of liquid glue covers 1000 sq ft of surface.

In contrast, the urea-resin mixture, employed in the new continuous-feed press, contains only approximately 30 per cent water.

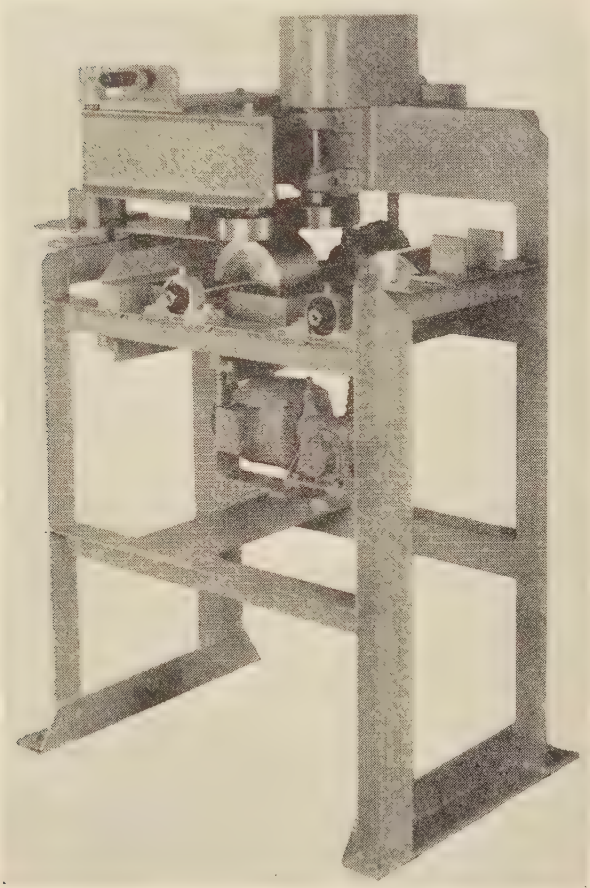

Fig. 1 Hand-Fed Core-Edge Glue Spreader

In addition, the resin glue is spread very thin, so that only about 30 to 32 lb of liquid glue cover 1000 sq ft of surface.

Therefore, it is quite obvious that the new edge-gluing method introduces only about one fourth the amount of moisture into the joint as that introduced by the conventional gluing method.
